Amenorrhœa following severe trauma, 1137
American Hospital in Paris, new wing, 154
American Journal of Ophthalmology (review), 133; of Syphilis (review), 917
American Public Health Association, fiftieth *annual meeting*, 500
American Therapeutic Association: Diathermy and galvanism in management of sequelæ of occlusion, 142—Sigmoid impaction; Diathermy as a therapeutic agent: Radium needles in treatment of malignant disease; Continuous current in inflammatory conditions, 143
American Year-Book of Anæsthesia *and Analgesia (1917–18) (Dr. F. H.* McMechan) (review), 864
Amœbic dysentery in a boy aged 3 (Dr. M. L. Young), 122; dysentery, 26
Amphibious boat-train, 1338
Amputations (Maj. F. M. Corner), 114
Anæmia, pernicious (Sir B. Moynihan), 160; local, comparative resistance of *tissues to, 396; acute aplastic (Dr. F. E. Larkins)*, 801; pernicious, 807
Anæmias, the severest, 979, 1048
Anæsthesia and Analgesia, American Handbook of (Dr. F. H. McMechan) (review), 864; Block, and Allied Subjects (Dr. A. E. Smith) (review), 1190
Anæsthesia, date of its introduction, 1112
Anæsthesia, psychology of (Dr. D. W. Buxton), 7; general, post-operative morbidity in relation to, 277; corneal (Ch. Coutela and A. Monbrun), 706; spinal, for suprapubic prostatectomy (Mr. H. M. Page), 800; Belgian methods of, 872; tracheal insufflation, portable apparatus for, 918
Anæsthetic, a new general, its theory and practice (Dr. R. L. M. Wallis and Dr. C. L. Hewer), 750, 1173; potent impurities in (leading article), 1194; inhaler, automatic, 1218
Anæsthetics in plastic surgery of the face and jaws, 136; examination of patients by the anæsthetist previous to administration of, 719; *purification of, a new preparation*, 750; *for an unusual* purpose, 819
Analytical Records.—Aseptoids, nasal comp., 390—Cod-liver oil, new season's, 758—Collosol ferromalt with cascara, 758—*Dimol, a new* intestinal disinfectant, 758—Energen gluten tapioca, (2) Energen enriched pastry flour with added gluten, 758—Ethanesal, 1309—"Fulcreem" products, 758—"Gadus" virgin cod-liver oil, 390—Glucose, pure, and pure anhydrous glucose, 390—Hémostyl, 1310—Lysol ward soap, 1310—Menthofax, 758—Metagen, 390—Quinosal, 1310—Oscol stibium, 390—Soaps, 758—Tuberclo vaccine R., 1309—*Turnwright's toffee de light, 1310*
Anaphylaxis and immunity (leading article), 1142
Anatomical study in Great Britain (Py Q), 911
Anatomy, Guide to (Miss E. D. Ewart) (review), 280; of the Human Skeleton (Prof. J. E. Frazer), second edition, 1920 (review), 335; the *Pocket* (Dr. C. H. Fagge), *eighth edition*, 1920 (review), 335; of the Brain and Spinal Cord (Dr. R. Whitaker), fifth edition, 1921 (review), 702; of the Nervous System (Prof. S. W. Ranson) (review), 1365; Surgical, Manual of (Mr. C. R. Whittaker), third edition, 1921 (review), 1365
Anatomy, morbid, revival of (leading article), 1249
Anatomy, patchwork, 297; *difficulties* of teaching, 1267
Ancoats Hospital, Manchester, report, 998
Anders, Prof. J. M., and Dr. J. S. Musser, Practice of Medicine, fourteenth edition, 1920 (review), 969
Anderson, Dr. Louisa G., appointed member of Central Committee on Women's Training *and Employment*, 336
Anderson, Dr. W. D., question of a trade-union in medicine, 989
Andrews, Dr. H. R., sarcoma of uterus, 526; carcinoma of the uterus originating in an adenomyoma, 1022
Aneurysm, after-results of ligature of *left subclavian artery for*, 223; *mycotic of the right calf*, 221; *involving* temporal bone, 276; of the aortic arch and innominate arteries, 386
Aneurysm, cirsoid, involving temporal bone and neck, 538
Aneurysms, palliative treatment by wiring, 596
Angina pectoris, action of heliotherapy *and phototherapy on the præcordial pain of*, 649; *in diabetes*, 658
Angioma of the spinal meninges, 175; of the vagina spontaneously evacuated, 1022
Aniline and cancer of the bladder, 713
Animal light, nature of, 56
Animals, diseases of, communicable to *man (Prof. F. Hobday)*, 720; *cancer in*, 984
Ankylostomiasis campaign in Egypt, 1913–1915, 1081
Annals of the Middlesex Hospital at Clacton-on-Sea during the Great War, 1914–19 (Mr. C. Berkeley and Mr. V. Bonney) (review), 1365
Anophelines, tree-breeding (Dr. B. Blacklock), 530
Antenatal clinic and placenta prævia, 938
Anthrax, inquest on a case of, *44*; *from* shaving-brushes, 289
Antimalarial operations in Albania, 556; measures in India (*leading article*), 1367
Antimony in the treatment of filariasis (Dr. G. C. Low and Dr. Elizabeth J. O'Driscoll), 221; tartrate, intravenous injection of (Dr. J. B. Christopherson), 522

Antiscorbutic factor, influence of aeration on (Dr. S. S. Zilva), 478, 938
Anti-serum, new, for tuberculosis, 397
Antitoxic serum, injection of and sudden death, 1371
Anti-Vivisection Hospital (Battersea General Hospital), meeting, 1219
Antler of the deer, growth and shedding, 236
Anxiety Hysteria (Dr. C. H. L. Rixon and Dr. D. Matthew) (review), 701
Anxiety psychoneurosis (Dr. A. Carver), 167
Aortic atresia, congenital, 803; disease (Sir J. Mackenzie), 1285
Aphakia in a human embryo, 1132, 1143
Aphasia (leading article), 1029
Apical disease, non-tuberculous, 871
Aplastic anæmia, acute (Dr. F. E. Larkins) 801
Apothecaries' Society of London, pass-lists, 152, 565, 1217
Appendicectomy, incision for (Mr. N. C. Lake), 268
Appendicitis, post-operative mortality of (Dr. H. H. Brown), 118, 201; in the sac of a femoral hernia, 925; and threadworms, 1316
Appendix, operation for removal in the *quiet time* (Mr. W. H. Battle), 313; clamp, new, 1310
Apperly, Mr. R., examination of patient by anæsthetist previous to administration of anæsthetics, 749
Appointments, weekly lists of, 53, 102, 154, 203, 254, 305, 354, 412, 465, 515, 566, 623, 674, 721, 782, 834, 888, 945, 999, 1053, 1109, 1159, 1220, 1276, 1335, 1392
Approved societies and voluntary hospitals (leading article), 654
A qui mieux mieux, 603
Archives of Radiology and Electrology (review), 1028
Arculli, Dr. H. el, acetanilide poisoning, 965
Arey, Dr. L. B., and Prof. C. W. Prentiss, Text-book of Embryology, third edition, 1920 (review), 702
Armistice Sunday, 501

Horder) (review), 388; Jurisprudence and Toxicology (Dr. W.G.A. Robertson), fourth edition, 1921 (review), 701; Electricity, Essentials of (Dr. E. P. Cumberbatch), fifth edition, 1921 (review), 1085; History, Annals of (review), 1244

Medical officers, divisional and whole-time (Py Q), 49; salaries (Py Q), 512; officers, district, for Scotland, 554; on China gunboats (Py Q), 670; Poor-law, position of, 673, 877; at Pensions Ministry (Py Q), 1217; and examination of ex-service men (Py Q), 1389

Medical officers of health and war bonus, 101; annual reports of, 144, 243, 346, 455, 505, 556, 823, 1383; and S.M.O., part-time or whole for, 249, 297, 350; district, status of, 1049; security of tenure for (Py Q), 562, 1318

Medical Officers of Schools Association, meeting, 18 (see also Medical Societies)

Medical profession, organisation of, 47; practice by foreigners in Spain, 58, 201; education in China (leading article), 392, 450; progress, French review of, 712; practitioners, sentences on, 717 practices, lock-up (Py Q), 1106

Medical record cards, Insurance (leading article), 84, 201, 248, 463, 461, 547; (Py Q), 562, 564, 671, 1036; and medical men (Py Q), 562; and Insurance committees (Py Q), 618; committee on (Py Q), 670; view of the London Panel Committee, 719

Medical service for Scotland, scheme of, a protest, 253; services at a voluntary hospital, payment for, 304; services in Aberdeenshire, coördination of, 717; service of the Defence Force, 1046; services, extension of, initiation of a county scheme, 1322

Medical works, early, catalogue of, 1000; article, how not to prepare, 1002

MEDICAL SOCIETIES.

Assurance Medical Society.—Albuminuria in relation to life assurance, especially in adolescents, 126

Brighton and Sussex Medico-Chirurgical Society.—Left-sided artificial pneumothorax, 253—Types of glycosuria and their treatment, 385—Valvular disease of the heart, 913

Bristol Medico-Chirurgical Society—Psychotherapy, 278—Shortness of breath, 439—Teething, 649—Surgery of the thyroid gland, 966—Exhibition of cases and specimens, 1260

Cardiff Medical Society.—Exhibition of specimens, 52—Experiments on the brain, 647

Devon and Exeter Medico-Chirurgical Society.—Exhibition of cases and specimens, 491—Nature and treatment of surgical shock, 966

Glasgow Obstetrical Society.—Methods of altering presentation and positions before and during labour, 913—Cæsarean section as a method of treatment in central placenta prævia, 914

Harveian Society of London.—Diseases of the œsophagus, 181—Future of the Poor-law infirmary, 276—Nævi in children and their treatment, 912

Liverpool Medical Institution.—Pathology of influenza; Use of antigonococcal serum, 27—Left-handedness and conditions associated therewith; Typhoid function in sick children and its influence on treatment, 126—Some of the rarer conditions of bones, 332—Tumours of the parotid gland, 439—Pathology of influenza, 593—Vascular lesions of the brain; Posterior rhizotomy; Diathermy and pharyngeal operations; Variations of the normal stomach, 648—Indications of blood transfusion, 752—Prognosis in patients presenting a rapid heart action, 753—Apparatus for mechanical distribution of various reagents in final Wassermann test; Blood group in infants and their mothers, 912—Antiquity of syphilis; Value of the electro-cardiograph in diagnosis and prognosis; Uses and limitations of the cystoscope; Cyst of the brain, 1025

London Association of the Medical Women's Federation.—Psychological forgetting in relation to lying, giving of evidence, and medical histories, 180—Influence of diet on dentition, 493—Circulation during and after acute infection, 596—Tuberculosis in children of school age, 862

London Dermatological Society.—Compulsory notification for venereal disease, 914

Manchester Medical Society.—Some aspects of preventive medicine, 913

Medical Officers of Schools Association.—Corporal punishment in schools, 699

Medical Society of London.—Exhibition of specimens, 174—Multiple neuritis, 273—Handprints of mental defectives, 274—Skin disease, its relation to internal disorder, 432—Chemical estimation of gastric function, 593

North of England Obstetrical and Gynæcological Society.—Exhibition of cases and specimens, 332, 494

Norwich Medico-Chirurgical Society.—Exhibition of cases and specimens, 753, 966

Ophthalmological Society of Great Britain (Annual Congress).—President's address, 1134—Cyclitis with glandular enlargement; Lamellar cataract with persistent pupillary membrane and birth injury; Flat neoplasm of the choroid; Symmetrical encroachment of the conjunctivæ on the corneal margins; Psychology of vision in health and disease; Evolution of visual perceptions, with special reference to the rôle of suppression, 1135—Amblyopia from disuse, 1136—Treatment of manifest concomitant strabismus, 1188—Iris-prolapse operation for glaucoma; Rational treatment of glaucoma; Extract of cataract by suction, 1190

Pathological Society of Great Britain and Ireland.—Fatal case of chorea; Hæmatemesis, 179—Hæmachromatosis; Malignant hepatoma, 180

Royal Academy of Medicine in Ireland (Sections).—*Medical*: Bubonic plague in Dublin; Acute leukæmia, 124. *Obstetrics*: Herpes as a type of vicarious menstruation, 124—Primary carcinoma of the vagina, 1133—Fibrous and muscular attachments of the vagina, 1134. *State Medicine*: Medical reform in Ireland, 491

Royal Glasgow Medico-Chirurgical Society.—Treatment of gastric and duodenal ulcer, 172—Hæmochromatosis and bronzed diabetes, 648

Royal Medico-Chirurgical Society of Glasgow.—Surgical treatment of chronic sciatica—Injury of the thoracic duct, 806—Digestion of the œsophagus as a cause of post-operative and other forms of hæmatemesis, 807—50 Cæsarean sections without fatality, 967—Exhibition of cases and specimens, 1136

Royal Society of Medicine (Sections).—Problem of the private clinic system, discussion, 1358

Anæsthetics.—Anæsthetics in the plastic surgery of the face and jaws, 436—Explosion of ether vapour during laryngoscopy; Importance of examination of patients by the anæsthetist previous to administration of anæsthetics, 749; Purification of anæsthetics, a new preparation, 750

Clinical.—Exhibition of clinical cases, 223, 802

Clinical, Medical, and Surgical (combined meeting).—Graves's disease, its medical and surgical treatment, 379, 486, 590

Electro-therapeutics.—System of X ray treatment of uterine carcinoma, 24

General Meeting.—Eradication of tuberculosis in man and animals, 643

Laryngology.—Exhibition of cases and specimens, 384, 593, 751, 1081; complete tonsillectomy as a routine operation; Operations on the frontal sinus, 1302—Site of origin of intrinsic laryngeal cancer; Paralysis of vocal cords in cases of malignant breast tumours; Diathermy in inoperable cancer; Ventricle-stripping operation for cord paralysis; Bronchoscopy in the treatment of asthma, 1303

Medicine.—Observations bearing on the ætiological classification of diabetes mellitus, 274—Thrombosis of the inferior vena cava; Tuberculosis immunising vaccine, 692—Artificial pneumothorax, 1182

Neurology and Ophthalmology.—Ocular palsies, 748

Obstetrics and Gynæcology.—Use of morphine in labour, 177—Inoperable uterine carcinoma treated by the cold cautery method of Percy, 178—Tuberculous peritubal cyst; X ray treatment of uterine fibroids and chronic metritis, 325—Exhibition of cases and specimens, 536, 1022

Ophthalmology.—Exhibition of cases and specimens, 225, 490—Variations in the size of the physiological cup and their relation to glaucoma, 225—Extreme choroidal atrophy in high myopia, 1131—Treatment of lacrymal obstruction; Aphakia in a human embryo, 1132

Otology.—Cavernous sinus thrombosis; Exhibition of cases, 275, 538—Zinc ionisation and electrolysis in the treatment of chronic otorrhœa, 538—Ears under modern war conditions; Device for tuning-fork testing; Lateral sinus thrombosis without otorrhœa, 750—Pathology of deaf-mutism, 1184—Sinusitis in children, 1185

Pathology.—Exhibition of specimens, 435—Experimental tar cancer; Standardisation of antipneumococcal serum; Attenuation of tubercle bacilli, 647

Psychiatry.—Mental tests, 489

Study of Disease in Children.—Exhibition of cases, 328, 1242—Congenital syphilis, 483, 695, 911

Surgery.—Further series of 500 goitre operations, 123—Repair of fractured mandible; Meckel's diverticulum as a cause of intestinal obstruction, 324—Treatment of imperfect descent of testicle; Cardiac massage, 1241. *Subsection of Orthopædics*: Exhibition of clinical cases, 383, 535, 805—Reactions and electrical treatment of the intrinsic muscles of the foot, 384. *Subsection of Proctology*: Pruritus ani, 859.

Tropical Diseases and Parasitology.—Prevention of tropical diseases, 538—Laboratory observations on pensioners who contracted malaria in the late war, 856—Large mononuclear leucocyte count as an aid to the diagnosis of malaria, 857—Mortality and prognosis of cholera treated by saline method, 1079—Ankylostomiasis campaign in Egypt, 1913–1915, 1081

War.—Snow-blindness, 24—Medico-military training, 694—Influenza in the navy, 1131

Royal Society of Tropical Medicine and Hygiene.—Exhibition of cases and specimens, 26—Influence of humidity on the life-history of mosquitoes and on their power to transmit infection, 330—Pathology of relapsing fever, 539—Fasciolopsis infection; Examination of chrysops for filaria in West Africa, 540—Trypanosomiasis, new method of treatment, 1185—Some points concerning trachoma, 1303—Early Portuguese contribution to tropical medicine, 1305

SCOTTISH SOCIETY OF ANÆSTHETISTS.—Post-operative morbidity in relation to general anæsthesia, 277—Exhibition of cases, 278
SHEFFIELD MEDICO-CHIRURGICAL SOCIETY AND BRITISH MEDICAL ASSOCIATION.—Venereal Disease Commission to the Far East, 753
SHEFFIELD MEDICO - CHIRURGICAL SOCIETY.—Does midwifery practice and teaching require reformation on physiological lines? 541—Palliative treatment of aneurysms by wiring, 596—Venereal Disease Commission to the Far East, 753
SOCIÉTÉ THÉRAPEUTIQUE DE PARIS.—Summary of papers, 227, 493, 494, 619, 862, 1211
SOCIETY FOR THE STUDY OF INEBRIETY.—Alcohol and industrial efficiency, 128
SOCIETY OF MEDICAL OFFICERS OF HEALTH.—Work of the Navy, Army, and R.A.F. group within the society, 25—Slum areas in Central London, 226—International organisation and *public health*, 437—*Relation of the* laboratory to preventive medicine, 698—Museum demonstration, 911—Meeting, 1331
Naval, Military, and Air Force Hygienic Group.—Improvements in hygiene of the *Royal Navy*, 437—Demonstration of sanitary appliances, 1132
Tuberculosis Group.—Influence of dust inhalation on the incidence of phthisis, 179—After-care of tuberculosis, *118*—Hospital treatment of acute and advanced pulmonary tuberculosis, 752
Welsh Branch.—Housing conditions, 699
SOCIETY OF MEDICAL OFFICERS OF MATERNITY AND CHILD WELFARE CENTRES.—Infant feeding after the ninth month, 861
SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.—Scheme of sickness insurance for ex-sanatorium patients; Standards of staff (medical and nursing); Coördination of statistics, 492—Training of nurses, 493—Reports, 860
SOUTH-WESTERN OPHTHALMOLOGICAL SOCIETY.—Squint problem, 697
TUBERCULOSIS SOCIETY.—Method of performing the cuti-reaction: Cultures of tubercle bacilli, 277—Rain-bearing winds and tuberculosis, 541—What we do *not* know regarding tuberculosis, 1305
ULSTER MEDICAL SOCIETY.—Hæmat*uria, surgical* aspect, 125—Injuries to the heart, 301—Election of officers, 1269
WEST KENT MEDICO-CHIRURGICAL SOCIETY.—Spina bifida; Manifestations of hysteria, 832
WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—Exhibition of cases and specimens, 180, 386, 807—Interim report of the Consultative Committee of the Ministry of Health, 227—Instrumental abortion, 700

Medical Society of London, dinner, 565; (see also Medical Societies)
Medical statistics, 985
Medicinal Treatment of Disease (Dr. R. D. Rudolf) (review), 968
Medicinal waters and X ray lesions, 1380
Medicine and industry (leading article), 83, 1260; reciprocity in (leading article), 186; dermatology in relation to (leading article), 391; collective voice of, 415, 550; industry, and research, 518; and the new Legislative Council, Madras, 611; man, a defence of (leading article), 655; comparative method in, 711; question of a trade-union in (leading article), 868, 933, 989; in the Southern Parliament of Ireland, 1157; industrial, conference of practitioners, 1260

MEDICINE AND THE LAW.—A medical witness and punctuality, 43—An inquest on a case of anthrax, 44—Assets of *the approved* societies; Importance of X ray examination; Copeland *v.* Orr; Massage establishments closed; Distributors of cocaine, 451—Alleged bogus doctor, 452—*Riders at coroners'* inquests, 610—Everett *v.* Griffiths and Anklesaria; A dangerous woman, 611—Defence of warranty in milk prosecutions; Question of irresistible impulse; Risks of a neglected cut; Need for compulsory cleanliness, 767—Evidence as to the time of death in murder trials—Property in bodily organs, 1041—What constitutes "breach of promise" by a panel doctor, 1096—Arsenic in borax, 1098—Certification of lunatics; Impotence quoad hanc, 1321

Medicine, place of pathology in, 1269; applied, institute of, 1318
Medicine, Preventive, Principle of (Dr. R. T. Hewlett and Dr. A. T. Nankivell) (review), 229; (Nouveau Traité de Médecine) (*Prof. G. H. Roger, Prof. F.* Widal, and Prof. P. J. Teissier) (review), 140; Series, Practical, Eye, Ear, Nose, and Throat (review), 410; Preventive, Practical (Dr. M. F. Boyd) (review), 495; for Nurses (Dr. J. Henderson) (review), 703; *and Disease* (*Die* Konstitutionelle Disposition zu Inneren Krankheiten) (Von Dr. J. Bauer), second edition, 1921 (review), 968; Medical Treatment of Disease (Dr. R. D. Rudolf) (review), 968; Practice of (*Prof. J. M. Anders and Dr. J. H.* Musser), fourteenth edition, 1920 (review), 969; in Vienna in the Past (Von Dr. M. Neuburger) (review), 1246
Medicine, relations of, to industry (leading article), 1250
Medicine, "*special*" internal examinations in, 339; the ideal element in (Dr. H. H. Bashford), 624, 675; preventive, relation of the laboratory to, 698; in India (leading article), 760; and the public, 783; in Soviet Russia (Prof. B. Sokolov), 874; preventive, some aspects of, 913; direct colour photography in, 1146
Medicines, Bazaar, Practical (Lieut.-Col. G. T. Birdwood) (review), 495
Medico-military training (Lieut.-Col. H. E. R. James), 683, 694
Melanoglossia, 922
Melbourne University, 929
Mellish, Mrs. M. H., Collected Papers of the Mayo Clinic (review), 967

The Huxley Lecture

ON

RECENT ADVANCES IN SCIENCE

IN THEIR RELATION TO PRACTICAL MEDICINE AND THE NUTRITIONAL REQUIREMENTS OF THE BODY.

Delivered at Charing Cross Hospital Medical School (University of London), on Nov. 24th, 1920.

BY F. GOWLAND HOPKINS, M.B., D.Sc.,
F.R.C.P. LOND., F.R.S.,
PROFESSOR OF BIO-CHEMISTRY, UNIVERSITY OF CAMBRIDGE.

No scientific worker, when invited by the staff of this great medical school to deliver a Huxley lecture, can fail in gratitude for the honour done to him. Nor, on the other hand, can he avoid a deep sense of responsibility. These occasions must be always significant, and till now each has been greatly served. The school has hitherto taken care that the memory of its great pupil should be recalled by lecturers, who have themselves reached high distinction. To follow them calls for courage enough. For myself, while offering my sincerest thanks for the opportunity put into my hands, I will beg for leniency, should comparisons be made.

I am to deal with human nutrition; but from a special standpoint and with special aims. I believe that recent acquirements in knowledge are changing the angle from which the nutritional needs of the human body ought to be viewed. That new criteria are becoming available and must be employed is the theme of this lecture. The acquirement of this newer knowledge began almost simultaneouly with the present century, but in its more significant, or, one should rather say, its more convincing aspects, it is of recent date. The latest developments were due almost entirely to investigators who have written in English. If they can be said to have yet affected practice it is only in countries where the English language is written and spoken.

I wish to put before you a personal appraisement of the importance of this newer knowledge, hoping to convince you that it has—as a subject of a Huxley lecture should, by definition, have—real relations with practical medicine.

As the last century closed the facts of nutrition were coming to be viewed more and more exclusively from the standpoint of Energetics. The criterion of an efficient dietary was apparently destined to be its caloric value, and, with one qualification, which seemed then to be lessening in significance, its caloric value alone. The chemical standpoint, in so far as it envisaged details, seemed to be losing its practical importance. Although the knowledge which was to correct these views, which, as I hope to show, were far too limited and exclusive, began to accumulate 20 years ago, the doctrine of the "eighteen-nineties" has continued to hold its ground, and is still sufficient for many.

Developments of Calorimetry.

Those years saw a remarkable development in the technique of human calorimetry. The accuracy with which the energy exchanges in the body came to be measured gave rise in the minds of all students of nutrition to a sense of real accomplishment, and to a feeling that, in addition to certain theoretical conclusions of great interest, calorimetry was making available, perhaps for the first time, information of a really quantitative kind to serve in practical guidance. The vague standards based upon statistical studies of the habits of communities could at last, it was felt, be checked, and if need be corrected, by data which were in the truest sense scientific. What, in terms of energy, are the basal requirements of the body? What the caloric equivalent of various forms of mechanical work? What the efficiency of the human body as a machine? What the relative value of different foodstuffs as sources of muscular energy? All these and kindred questions were being answered or the methods for their future solution made clear as the last century closed. They are, indeed, still being investigated, and with increasing accuracy, chiefly in the country where they were first seriously dealt with. For American workers Graham Lusk, Dubois, Benedict, and others are continuing the work of Atwater and Rosa, and are obtaining quantitative data which can be so controlled as to carry their own inherent proof of striking and even startling accuracy. The investigations are extending into the domain of pathological metabolism, and there I am convinced will have important bearings. I should, indeed, stultify myself if any word in this address gave you the impression that I under-value the results of accurate calorimetry as applied to man. My contention will be not that the data of calorimetry are unimportant, but that they are insufficient. Whatever else we need to know for proper definitions of nutritional requirements, we need always to know what is the call for energy. It would have been well indeed if the importance of such knowledge had been more widely recognised by Governments before the war. In spite of the developments I have mentioned, the war and its very urgent needs for guidance in matters of alimentation found us still with far too little knowledge of the energy requirements of troops in the field and of individuals engaged in various employments. It was as painful for those who had, in any capacity, to give advice to administrators on such matters to realise that scientific information was still sadly lacking in detail as it was surprising (at first) to the officials that scientific men should have any information to give at all! Considering the mass of information that is wanted and the fact that up to now the necessary equipment for such studies is confined to a few centres in America, it is not surprising that the data for complete practical guidance are even yet lacking.

Importance of Chemical Details.

If, however, when the crisis arose, the information available for guidance was insufficient on the side of energy requirements, the advice which could be given was lacking in precision for quite another reason. There was too little knowledge concerning, or, where there was knowledge, there was, for a long time, too little faith in the facts which later are to form the theme of this lecture. It is in my opinion not too much to say that when peace was established if policy had recognised, and could have afforded to apply, the teaching of the facts in question, the nutrition of Central Europe would be in a greatly more satisfactory condition than it is.

You cannot fail to have gathered already that my purpose is to bring to the front the importance of chemical details in the science of nutrition. Only by full consideration of these are adequate criteria made available for dietetics. I may take as my text the following definite and unequivocal statement:—

An animal may receive, digest, absorb, and, in a sense, fully metabolise a diet consisting of all the recognised basal foodstuffs. It may be taking these foodstuffs in quantity sufficient, or more than sufficient, to supply all its needs for energy. And yet its nutrition may be so abnormal that neither growth, nor health, nor life is long maintained. That this statement is one of fact has been brought home to many engaged in experimental studies by the behaviour of hundreds of individual animals. Being true it shows at once that, however useful may be the criterion of energy values in food-supply when other essentials have been first secured, the energy it contains cannot be the sole criterion of a diet. We cannot indeed escape from a full consideration of detail.

It is always a delight and relief to the mind when by the generalisation of knowledge it is enabled to neglect details. This relief is given in many branches of science by the application of the principles of energetics or thermodynamics. The method of thermodynamics, as you are well aware, enables us to make certain quantitative statements concerning physical and chemical phenomena without any kind of reference to the molecular mechanisms which underlie the phenomena. The statements remain true however

No. 5079.

much our views may change concerning the mechanism. Defining the nutritional needs of the body in terms of calories is an application of the thermodynamic method to metabolism. In a very limited sense, however. The true thermodynamic of metabolism calls for consideration of each tissue separately. Statements in terms of calories refer to a balance of events in the body, and refer alone to the energy liberated by combustion of the foodstuffs. On fuller analysis we may find that a given tissue utilises the free energy of a foodstuff and not its energy of combustion alone. Such considerations would lead me, however, to stray from my path. I would just like to point out here as noteworthy the fact that physical science in its recent dealings with the atom has returned to the study of mechanism, and that what we may call the higher chemistry, after long pre-occupation with thermodynamical studies, has come back with fresh interest to considerations of molecular structure.

Rubner's Law of Isodynamic Equivalence.

I am on the present occasion more anxious to convince you of the real and significant difference which exists between the outlook now opening and the narrower one which sufficed till recently, than to present at any length the more technical side of modern studies. I will venture therefore to delay my dealings with the new facts just a little longer in order to show how the older view has, both in theory and practice, been narrowed to the utmost. I will derive my discussion from the teaching of two authorities of the highest standing. I allude to Rubner and to von Pirquet. The one (though no mere theorist) shall supply the doctrine. The other (though far from an empiric) shall illustrate practice.

Rubner, however one may appraise his theoretical teaching, is one who has done more than most to advance the science he professes. He was the first to offer acceptable experimental proof that the principle of the conservation of energy holds in the animal body. A pioneer in calorimetric studies, he rightly saw that the conception of energy changes expanded and corrected certain of the earlier and purely material conceptions concerning life and its maintenance. But he also gradually developed a doctrine in which the energy exchanges of living matter are supposed to give, as it were, a higher and more significant criterion of life than any consideration of material changes could provide. From much of Rubner's teaching one gets, indeed, the impression of a belief that any broad and philosophic view of the meaning of life can only be obscured by attention to the details of material.

In one of his expositions[1] Rubner poses the question: "Material or Energy, which (in nutritional phenomena) is the more decisive?" and straightway answers the question by reference to the law (so named by him) of Isodynamic Equivalence. This involves the principle that any one foodstuff can replace any other so long as the replacement makes no change in the supply of energy. We may place, continues Rubner (I quote almost verbatim) a warm-blooded animal—a dog, for instance—under absolutely constant conditions and nourish it respectively with protein, with fat, or with carbohydrates. Now the chemistry of its nutrition in those three cases is wholly different, and the weight of material which we must administer to maintain the identity of conditions is by no means the same. If, however, we determine by calculation how great is the consumption of energy we shall find it constant in each case. Here is the proof of the Law of Isodynamic Equivalence. So argues Rubner; but unless the above statements are interpreted under strict limitations they are simply not true, and they may be made the basis of false doctrine.

Rubner, for instance, in the same place proceeds to assert "From the Law of Isodynamic Equivalence it follows that the living tissues do not demand any one of the basal foodstuffs in particular, but demand energy alone," a doctrine which on any fair interpretation is false. Permit me, however, to follow the thought of this author a little further. Rubner has maintained certain general propositions concerning living matter which, if true, are certainly of interest. The first is this: Every unit of living matter (a unit which it is not easy to define), is adjusted to expend the same amount of energy in a given time. If in different cases the expenditure seems vastly different it is due to circumstances alone. Make the circumstances the same and the energy expenditure will be the same, whatever the origin of the living unit, whether it be part of a bacillus or of a man. This is one way of stating a theory of life's unity. One need not quarrel with it. It is, however, almost impossible to prove it experimentally, and I doubt if it has any greater value than, say, the statement that there can be no life without phosphorus.

The next proposition takes us further into dogma and further away from the region of experimental proof. It is that when the unit of living matter has expended a certain predetermined quantity of energy it ceases to grow. This, again, if we follow Rubner, is to be taken as a fundamental attribute of living stuff. It follows that the duration of growth and the ultimate size of any animal are both functions of the rate of energy exchange in its tissues. The "tendency to grow" is just as great in the tissues of the young mouse as in those of the young elephant. Consider, however, two units of living matter, one of which is, or is to be, part of the body of a mouse, and the other part of the body of an elephant. From the first their condition, from the standpoint of energetics, is very different. The former, when in utero, is part of a material system (the body of the mother) which, being small, has relatively to its mass a large surface. Because of this relatively large surface energy (heat) is lost to the environment with proportionate rapidity and energy liberation within must be rapid for the maintenance of equilibrium. The latter, the embryonic elephant, is from the first part of a large system, of which the surface in relation to its mass is small. The rate of loss to the environment is therefore in this case proportionately small, and energy expenditure is economical. When mouse and elephant are born their own masses are still proportionately small and large respectively, the units of living matter within them suffer therefore the same differences of condition. In the small mass of the young mouse heat production must be rapid, in the larger mass of the young elephant it is slower, and so throughout their growth. But the doctrine, as you have heard, is that living matter has only a certain limited heritage of energy to expend before growth must cease. In the mouse compulsory extravagance shortens the growth period; in the elephant an equally inevitable economy makes the growth period a long one. Hence, according to Rubner, the ultimate smallness of the mouse and the largeness of the elephant! This is pure dogma. In certain of its aspects there may be truth in the dogma. But there is just as much actual evidence, and in my opinion more inherent probability, for the view that variety in size and form is determined by the specific chemical differences in living matter. Rubner voices his belief that duration of life is also inversely proportional to the rate of energy expenditure; but I must not consider his doctrine any further. He is no vitalist; he is far from postulating a special life force; but in his endeavour to extract some criterion of life other than its material basis he so sublimates the conception of energy—isolating it from and setting it above its material associations—that one feels we are almost brought back to the Archæus of Paracelsus. In parenthesis we may note that another modern mind of a very different type and from a very different standpoint has urged that no significance need be attached to any particular material basis for life. Henri Bergson, who postulates that only two things are necessary for the manifestation of life: (1) an accumulation of energy, and (2) an elastic canalisation of this energy in variable channels at the end of which are free acts, writes as follows:—

> "This two-fold result has been obtained in a particular way on our planet. But it might have been obtained by entirely different means. It was not necessary that life should fix its choice mainly upon the carbon of carbonic acid, ... and if the element charac-

---

[1] Kraft und Stoff im Haushalte der Natur, Leipzig, 1909.

teristic of the substances that supply energy to the organism had been other than carbon the element characteristic of the plastic substances would probably have been radically different from what it is."

All this is as it may be. I have naturally on the present occasion no direct concern with M. Bergson's philosophic views, but it is of some interest to see a philosopher and an experimentalist meet together on the ground that the chemical materials with which life is associated are, relatively speaking, of little significance. This ground is, of course, well worn. It is only that the two modern thinkers I have quoted have reached it by rather special paths. The essential view is old. In one of the most famous of his addresses, delivered in 1868 and well known to you all, Huxley remarks: "I suppose that to many the idea that there is such a thing as physical basis or matter of life may be novel—so widely spread is the conception of life as a something which works through matter, but is independent of it. ......" Huxley, needless to say, controverts that view.

But for the moment I will pass from theory to practice. I will refer to practice which is based upon doctrine such as that of Rubner, but on its sounder parts alone. The reference might come better later; but I want you to have it clearly in mind at the moment that the standpoint of energetics is still dominant in the highest quarters. It is because of this dominance, indeed, that I was led to my choice of subject for this lecture.

Von Pirquet's "Nem" System.

The name of von Pirquet is familiar to you all, and from the scientific standpoint carries with it the very highest respect. It is associated with many important advances in medical practice, but in particular with a remarkable organised system of alimentation. This system—the "Nem" system—involves the rigid application of scientific principles (as appraised by its originator) to the alimentation of individuals, on lines that are ingenious, thorough, and organised for high accuracy. Primarily meant for hospital patients, the system is capable of extension to all classes of the community, and is, indeed, being employed under the direction of Professor Pirquet at this moment in the remarkable task of feeding, on behalf of the Red Cross Organisation, nearly 200,000 children in Vienna. It is based primarily upon calorimetry, aided by calculations which deduce the energy requirements of an individual from his body-weight and his sitting (not his standing) height. In place of the calorie, of which the definition is too abstract for the public, a more objective unit is employed. This unit is the energy contained in 1 c.cm. of milk and is known as a "nem."[2] His or her energy requirements, having been determined on the lines just mentioned, each individual under the system is supplied with a corresponding dietary as evaluated in nems. 10 per cent. of the energy is supplied as protein, but no critical attention is paid to the actual composition of the diet. If, for instance, fat be scarce, as at the present time, then it is replaced with sugar. The practice is based, frankly and courageously, upon energy value as the essential criterion of nutritional efficiency. We have therefore at one of the chief foci of science in Central Europe, at a time when economy in nutrition is a most urgent need, a system which ignores chemical details in diet. Now, if there be anything of significance in the considerations which are to engage your attention this practice must be seriously wrong. I shall return to it again before closing my remarks.

You have now been reminded of the theory and practice which form the point of departure for the newer conceptions. These shall now be appraised.

Impossibility of Replacement of Fundamental Foodstuffs.

During the discussion of Rubner's views it must have been in the minds of most here to ask how that author deals with the protein question. For three-quarters of a century it has been known that protein is one of the specific needs of the body. Protein for repair; fat and carbohydrate for fuel—that has been the short formula which, ever since the times of Liebig, has satisfied the majority of those who deal superficially with nutrition. It is an unsatisfactory formula; but at least it does not ignore the fact that there is one necessary item with specific chemical characters. Needless to say, Rubner has not ignored protein in connexion with the practical side of his scientific work, but while developing the sublimated views that have been put before you, he is content to point to its quantitative unimportance. No more than some 4 per cent., he urges, of the total energy demands need be supplied in the form of protein. But in dynamic phenomena, such as those which underlie nutrition, the significance and importance of a factor are not measured by its amount but by its indispensability; and no standpoint, it seems to me, can have either theoretical or practical value when it ignores this fact.

Recent researches, as I shall immediately remind you, have added much to an understanding of the significance of the protein element in nutrition; but a more general aspect of the case first requires brief attention. The basis of the doctrine of Rubner and those who think with him is, as we have seen, the claim that one foodstuff can replace another without disturbance to nutrition, so long as the energy supply is unaltered.

Whatever of truth may reside in this so-called law of isodynamic equivalence, as a bald statement it involves a suggestio falsi. No one of the fundamental foodstuffs can completely replace any other, even when the replacement involves no change in energy value. The closer the study of its needs the greater becomes the assurance that a certain minimum of each basal foodstuff is essential to the body. It is seldom desirable to speak of a "law" in biological science, but if we are to use the word at all we may say that in the phenomena of nutrition the law of the minimum overrides the law of isodynamic equivalence. True, it is important to avoid confusion of thought here. Whatever is fully oxidised in the body yields, of course, as it would yield elsewhere, heat equivalent to its energy of combustion. In that limited sense, isodynamic equivalence is involved in the principle of the conservation of energy, which assuredly holds in the body. But the efficiency of every working mechanism demands that the liberation of energy within it should occur in the right place and at the right time. Now the material body is a working system of such a kind that the most influential factor in determining where and when energy shall be liberated within it is the precise chemical nature of the fuel it burns. Not only, then, for the maintenance of its specific chemical structure and for its equipment as a laboratory, but also for the due ordering of its traffic with energy does the body call for a certain harmony and balance in the chemical nature of the materials which it receives from the environment.

Limits of Interchangeability.

Even when we think only of the three basal organic foodstuffs it is by no means true to say that so long as a minimum of protein is supplied the body is indifferent to other interchanges of material. For many years we have been well aware that it is not true at the limit. If carbohydrate be entirely replaced by fat metabolism fails at a crucial point. Complete utilisation of the energy in the fat does not occur. The chemical side of this failure is expressed in the phenomena of ketosis. Ketosis by itself proves that isodynamic equivalence amongst foods is at best a much limited principle. But other facts bear on this question. If carbohydrate and fat were nutritionally interchangeable both should serve equally well as a source of muscular energy. The best evidence available shows that they are not. The point has been very recently investigated afresh by Krogh and Lindhard,[3] of Copenhagen, and their experiments seem to me the most critical and conclusive of any in the literature. They were led to undertake the investigation because of some work done at Cambridge on isolated muscles, the results of which seemed to show that a muscle cannot be indifferent to the form in which its energy is supplied. The Danish observers found that the human body performs work more economically upon carbohydrate than upon fat, and when the work is sufficiently severe it is performed with greater difficulty upon the fat and occasions greater fatigue. When fat largely predominates over carbohydrates in the food there is a wastage during work of some 11 per cent. of the energy contained in fat. It is not liberated in the right place. Another interesting aspect of metabolism seems to be indicated in this research. We have known that a certain minimum of carbohydrate is required to secure full utilisation of fat. The converse would seem to be true; a certain minimum of fat is necessary for the proper usage of carbohydrate in the body. Although within certain limits these two foodstuffs may be interchangeable limits definitely exist. It is likely from the facts that there exists some proportion between them which would best suit ideal nutrition, but we do not yet know what this may be. It is, at any rate, clear that while the law of isodynamic equivalence is far from having that absolute character which would give it theoretic importance, it may well also fail as a guide in practice.

Protein Supply.

I come now to the still more significant question of protein supply. Just as this century opened marked advancement in the chemistry of proteins began and rapid progress continued. In a few years, aided by new physiological and nutritional studies, which it made possible and stimulated, this particular advance in chemistry greatly increased our grasp of the meaning of nitrogenous metabolism, and our understanding of a most important side of nutrition. It is, indeed, not too much to say that this better knowledge concerning the constitution of these fundamental constituents of living tissues has already exerted a wide influence in all biological science, and in my opinion its ultimate effect will be wider still.

It is, of course, out of the question that I should deal with this advance historically, or allot credit to the many who have helped in it. I can perhaps best remind you of what in this newer knowledge is essential to my theme by rehearsing a few concrete statements.

1. We know that the complex molecule of protein consists of some 20 structural units assembled in what we may call the molecular pattern of the protein. All of these units belong to one chemical genus, since all are residues of α-amino-acids; but each represents a species within the genus, since each has elements of molecular structure which differentiate it from all the rest. The fact that all these units have certain characters in common, and the circumstance that they nevertheless differ so widely, are equally significant in the phenomena of metabolism.

2. In the molecular patterns of diverse proteins any individual unit may occur, in the one case seldom, in another many times, as might be the case with tesseræ of a particular colour in different mosaics. This decides the percentage yield of any particular amino-acid—say tyrosine—when this or that protein is digested. Sometimes, though rarely, a unit or units may be absent from the molecular pattern. The chief protein of maize, for instance, yields on digestion neither lysin nor tryptophane, though these amino-acids are among the score yielded by most proteins.

3. It is the molecular pattern—the arrangement, not the nature, of the constituent units—which differentiates the proteins of different tissues, and, so far as they are different, the proteins of homologous tissues in different species. Such differences are fundamental and underlie morphological differences in plants and in animals.

4. In digestion the pattern of the protein consumed is destroyed. The hydrolytic processes in the alimentary tract liberate the constituent amino-acids, and these, for the most part, if not entirely, are free and individual when, by way of the blood, they reach the tissues. In constructive processes the units are rearranged in patterns peculiar to the proteins of each tissue. Specific characters are thus maintained whatever protein may be eaten.

5. An animal can be maintained indefinitely if instead of intact protein it be given the whole mixture of amino-acids which results from the complete digestion of a normal protein such as the casein of milk. This fact makes it possible to test the nutritive importance of each individual amino-acid by observing the effect upon the animal of removing it, and it alone, from its food. By this method it has been shown that the body can dispense with certain parts of its food protein—usually the amino-acids of relatively simple structure—because it can make them for itself. On the other hand, with others it dispenses less easily, and some—usually the more complex in structure—prove to be wholly indispensable, and must have a certain minimal representation in the diet.

6. It should be understood that the function of any individual amino-acid need not be confined to its share in the reconstruction of tissue proteins. It may be the indispensable raw material for more specific chemical processes. As a single instance of such a function it may be noted that the iodine of the thyroid gland is present in an indol compound. One particular amino-acid from protein, tryptophane, is itself an indol derivative, and almost certainly is constantly required for maintenance of the thyroid function.

7. It follows from all this that nutritive values require, in the case of proteins, definition in detail. The minimal amount of a given protein which is adequate for maintenance will depend upon the amount it contains of that particular essential amino-acid in which it is most deficient. Different proteins may thus have very different nutritive values, a fact which may be, and has been, directly and very fully proved.

The body, therefore, in a given case may suffer from defect in the quality rather than from deficiency in the quantity of protein eaten.

Vitamine Supply.

But as was urged earlier in this lecture nutrition may wholly fail even when the supply of protein, no less than that of the fat, carbohydrate, and minerals is perfect. In such a case we should nowadays look to a deficiency in vitamines. I wish I might prove able to put the subject of vitamines or accessory food substances (as earlier in their history I ventured to call them) in the right light and in proper proportions.[1] The subject is no longer in a strict sense new, but its practical importance needs, perhaps, appraisement. Believing personally that the nutritional function of vitamines is a most significant fact, with important bearings in practical medicine, I yet recognise that when wide claims are made for this view a critical attitude may still be justified.

The chemical nature of vitamines remains unknown. As such they have never been isolated. Now one can quite well understand the consequent attitude of the practically minded. An agriculturist, concerned with the feeding of stock, assured one of my colleagues that he would believe in vitamines only when their price per hundredweight could be quoted in the market. One can sympathise with this practical attitude, but one sympathises less with the scientific man who refrains from an endeavour to appraise their importance until such time as when they have been separated in a pure condition. To be logical he should then avert his eyes from such agents as toxins and antitoxins, not to speak of enzymes; powerful realities all of them which, though of unknown constitution, by no means elude objective and quantitative study. It is doubtless easier for those who, like myself, have seen the facts illustrated by the fates of hundreds of animals, to believe that the whole difference between complete failure of nutrition on the one hand, and perfect nutrition on the other, may depend upon the presence of uncharacterised materials in amounts which, while not infinitesimal, may be extraordinarily small.

Though the history of knowledge might well forbid the question, it may be asked, How, if the influence of such factors is so important, can they have eluded observation till now? Discriminating studies of human nutrition in which scientific thought has been applied to quantitative observations, or at any rate those recorded studies which make up the orthodox literature of the subject, had mostly been made at centres of learning, situated among communities receiving that variety of food which is characteristic of Western civilisation. Strong suggestions for the importance of details are under such circumstances lacking, for the necessary details are automatically supplied. Suggestions, sometimes vague, sometimes really clear, have, as a matter of fact, been frequent enough in the writings of those who in the past have been responsible for the feeding of communities when stress and shortage exist, or when, as on voyages of discovery, food has become abnormal or restricted in kind. As you know, it was from the East, where diets are more one-sided, and the security due to compensatory variety much less, that some of the more important of the evidence came to justify the newer conceptions that are now establishing themselves.

---

[1] I can make no attempt to deal with the literature of vitamines, and those who have advanced the subject will, I trust, excuse the absence of reference to their labours.

The experimentalists of the last three-fourths of a century, though they have thought in terms of proteins, fats, and carbohydrates, have never given these substances to their subjects in pure form; otherwise they would long ago have learned that they alone could not maintain organic nutrition. They gave natural foods, while ignoring, for the most part, the fact that such foods, being themselves plant or animal tissues, contained a great number of substances other than the basal protein, &c. Yet the nutritional value of these surely called for study. Most of these other substances, however, are present, individually, in small amount, and it will be readily understood that, so long as the tendency to view nutrition more or less exclusively from the standpoint of energetics was wholly in the ascendant, the minds of the students were averted from a consideration of substances which could contribute so little to caloric value.

But while the animal so clearly depends upon the plant, which alone can trap solar energy, for its supply of calories it depends upon the latter no less for highly specific materials. The urgent need for certain amino-acids is sufficient proof of this. But there was no logical reason for the tacit assumption that this need could extend only to substances which, like the protein constituents, or the fat and carbohydrates, are made by the plant in relatively large quantity. A few experimentalists have, it is true, set themselves to discover if any of the known minor constituents of natural foods—that is, in the ultimate tissue, the minor constituents of plant tissues—are of nutritional importance. It is now sure that the animal body can dispense with every one of these which happens to have been isolated in a pure form; with every one which is, in the strictest sense, known. It may be a coincidence or there may be chemical reasons for the circumstance that the highly active constituents have escaped isolation. It is at any rate among the unknown minor products of plant life that substances indispensable for the animal are found, and these we call vitamines. There is, in fact, at present no other definition of a vitamine as a nutrient, but what is based upon its indispensability, its very low effective concentration, and, if you will, our ignorance of its chemical nature. Doubtless had such substances been easy for the chemist to isolate they would have been isolated long ago, and a knowledge of their chemical nature might well have preceded the knowledge of their nutritive importance. The sequence was fated to be the reverse of this. At any rate, it is quite sure that there is no fear in this connexion that the known is masquerading as the unknown. Some seem to have suspected this possibility, but the crucial experiments have been far too discriminating. The technique used in the study of vitamines has now indeed some elements of exactitude. They can be removed from diets, and restored to them in a high degree of artificial concentration. They display specific properties sufficient for clear distinctions to be made among them, and more than sufficient to prove that they belong to chemical categories different from those containing the better-known foodstuffs.

I have been so far concerned to point out that, while there is no great reason for surprise in the circumstance that studies of nutrition, made on lines that had become orthodox, did not earlier lead to any conception of nutrients of the vitamine type, there is also no reason at all for surprise in the fact that substances with the qualities ascribed to them do, after all, exist. There is, perhaps, on the other hand, some reason for surprise when we find that the quality which, as I have said, really serves at present to define them is displayed to so high a degree. I mean their power of exerting a nutritional influence altogether out of proportion to their concentration in the food.

You will not expect here any technical discussion concerning these substances. This lecture is covering too wide a ground for my remarks to have other than general bearings. I would only remind you that at present three vitamines are known, to each of which I must refer in a later brief discussion of deficiency disease. It is quite likely that others exist, and their discovery may make clearer certain aspects of faulty nutrition, which are yet obscure.

The Law of the Minimum.

I would ask you at this stage of the discussion to note how very far the more newly won facts, especially those concerning the protein and vitamine supply, have carried us from the doctrines earlier discussed. Contrast Rubner's claim that the animal body makes no demand for specific material but only for energy, with the fact that when deprived of materials which contribute at most some few hundredths of its total food, the body fails altogether to make proper use of other of the energy supply. Rubner and those who think with him would speak of energy supply as the one essential "limiting factor" in nutrition. What we have actually to recognise is that each of several factors may become that which limits efficiency, and that no one of these is in any strict sense more important than any other. Normal nutrition calls for a certain minimum of each one and every one. If a diet is harmoniously balanced in a chemical sense, then indeed energy does become the sole limiting factor. Nutrition then fails, of course, only when too little of the diet is eaten to yield the essential minimum of energy. But the supply of fat may become the limiting factor, and no less that of carbohydrate. Or, again, when the supply of energy consumed is ample, with fat and carbohydrate duly adjusted, the circumstance that a single essential amino-acid in one case, or a vitamine in another, is present in amount below the necessary minimum converts each of these in turn into the factor which limits utilisation. Small as the necessary minimum in either case may be, unless it is reached the proper use of the rest of the diet is reduced to a degree which is proportional to the deficiency. If the deficiency be complete normal utilisation is altogether impossible.

This is a statement of the working of the Law of the Minimum, a much more significant principle in nutritional phenomena than the Law of Isodynamic Equivalence.

It is of course true that in civilised and prosperous communities the large variety of foods upon the market and the natural instincts of those who can afford to purchase them, secure for the most part the consumption of well-balanced dietaries, so that when, say, the requirements of a particular calling in such a community are to be estimated, energy measurements yield a justifiable criterion. It is nevertheless important to remember that even in the midst of plenty individuals, and even communities, may consume chemically deficient diets, and a proof that their energy consumption is normal may then lead to very wrong conclusions.

Under special conditions of existence the protection afforded by variety in food may so fail as to make possible dramatic consequences in the form of deficiency disease.

Scurvy and Food Deficiency.

The conception that a specific disease may be due to a specific deficiency in diet appealed to some, even long ago, as involving, logically, a possibility. For many who have passed through certain experiences—the conditions of war contributing—the possibility has become a fact. Others, however, still accept the available evidence for the existence of this particular case of cause and effect with considerable reserve. To me the phenomena of scurvy in the adult have always seemed to provide a touchstone. They were surely sufficient to justify belief in one deficiency disease at any rate long before it was supported by other evidence. It will, indeed, further the aims of this address if I ask you to consider a little the case of scurvy, familiar as it is, even at the cost of my giving insufficient attention to other cases.

The element of drama seems always to be present in the literature of scurvy, be it in professional writings or when, as long ago used often to be the case, it inspires the pens of the laity. No one can read some of these earlier records of the disease at its worst—for instance, the account given by Richard Walter, Anson's chaplain on board the *Centurion*—without something of a thrill. But though its ravages were greatest on the old slow-sailing ships, cut off from fresh foods for long weeks together, it was common enough two centuries ago among certain communities at home. It is of interest on this occasion to recall a remark made by Huxley when writing of David Hume. Huxley, recalling that during one period of his early life Hume developed symptoms of scurvy, speaks of it as "a disease now almost unknown *among* landsmen, but which, in the days of winter salt meat, before root crops flourished in the Lothians, greatly plagued our forefathers." In Hume's case there was a dramatic disappearance of the disorder. His circumstances improved, he developed a voracious appetite, and in six weeks, Huxley reports, from being lean and raw-boned (and scorbutic) he became sturdy and robust, with a ruddy complexion and a cheerful countenance.

But it is, of course, in naval records that the dramatic side of the disease is most evident. We will think, however, only of the successive acts in the story of prophylaxis and recall, first, how, after being a heavy scourge, scurvy practically disappeared from the ships, when, in 1796, the wisdom of Sir Gilbert Blane decreed a ration of lemon-juice for all and sundry. In the second act of the drama scurvy reappears. The fruit-juice was thereupon gravely discredited; but fortunately a prophylactic of quite different sort made the tragedy less. Steam was soon to carry the mariner, more swiftly than could sails, to ports and supplies of fresh foods. The last acts in the story are recent. Science at the Lister Institute demonstrated that the juice of one variety of citron is not the same as that of a related variety. The historical research of Mrs. Henderson Smith brought this knowledge into relation with the story of scurvy in the navy. The juice which had protected everybody so well at the end of the eighteenth century, and during the first half of the nineteenth, was that of sweet limes and lemons. When the trouble reappeared it was because for economic reasons the juice of the West Indian or sour lime had been substituted. But the latter has now been shown to contain only a fraction of the amount of the antiscorbutic vitamine which is present in the former and contains it in a less stable form. Surely this is an interesting correlation in circumstance. I have dwelt upon the matter because it clearly shows how specific may be a material bodily need: need for a substance produced in all plants but of such a special nature that it may be freely stored in the fruit of one variety of a species, but scarcely at all in that of a related variety! And I dwell upon the history of scurvy generally because it illustrates so well how a bias or habit of mind (so, at least, it seems to me) may affect thought about ætiology.

As Surgeon Rear-Admiral P. W. Bassett-Smith has pointed out,[5] Blane, a century and a quarter ago, attributed the disease to the lack of a "certain element which is necessary for growth and repair" thereby foreshadowing definitely enough the conception of a deficiency disease. But the great naval hygienist saw much of scurvy and its remarkable response to treatment. Later authorities have often seen much less and speculated more. If they could discard for a moment the obsessions of intoxication and infection and accepted the obvious significance of diet in scurvy, they thought only in terms of the known, and looked, for instance, to the absence of potassium salts or the organic acids of fruits as the causative factor, oblivious of the fact that the stability of such substances ruled them out of all relation. But up to quite recently, though not, I think, since the coming of the impressive evidence made available by war conditions, there have been many struggles to bring scurvy back into the category of infection or intoxication. I put it to you (as counsel would say) that, considering the nature of the evidence, such endeavours can only be due to the obsession that some positive agent—some intruder so to speak—must always dominate ætiology. Several recent writers, concerning themselves with the definition of deficiency disease, have criticised the use of the term "negative cause" and doubtless to formal logic such a term would be abhorrent. But it is better to use a somewhat illogical term than to miss some solid meaning which is conveniently conveyed by it. We must either speak of the cause of scurvy being the absence of something from the diet, or, because of its casuistic accretions, avoid the word cause altogether. Objection to a term is a small matter, but apparently with some the objection involves the practical standpoint that the production of phenomena like the symptoms of disease can only be due to the influence of some positive factor. If not to a poison or to infection, then to excess of something. Certain authors find it logical to refer causation to excess, but illogical to refer it to defect. They feel perhaps that the latter course takes liberties with the old adage "Ex nihilo nihil fit." But do not such views carry us back to the popular or metaphysical conception of cause as enforcement, and away from the scientific conception of cause as the routine of experience? Causation, in the words of John Stuart Mill, is recognised by uniform antecedence.[6] Antecedent to normal nutritional phenomena is the consumption of a particular set of essential nutrients. If in the absence of one of them the sequence proves to be consistently different, such absence is then the reason (for we may avoid the word cause) for that difference. So we may say the reason for scurvy is the absence of the unstable antiscorbutic vitamine, and it is a sufficient reason.

But through long years, so notable in other respects for great advances in knowledge concerning the origin of disease, the pointings of scurvy failed to give rise in the modern mind to any clear-cut conception that the body, being a chemical system depending upon the law of the minimum, might well lose its equilibrium for lack of some minor but perfectly specific dietetic factor. It required other evidence to give birth to the conception. This came in the first place from an intensive study of the relation of diet to another disease—beri-beri. The final issue here has been a practical certainty that the symptoms arise from a different but equally specific failure in supply—the lack of the so-called water-soluble vitamine. But had the further evidence come alone from the pathological side it is doubtful if it would have compelled the arrival of a general idea. At the same time, however, proof was being provided, as we have seen, that apart from any manifestation of disease normal growth and maintenance fail in the absence of the same or similar factors of supply. Under the compulsion of all the facts the idea of a vitamine crystalled out, and carried with it the understanding that deficiency might be a real element in the ætiology of disease.

Fat-soluble Vitamine.

An essential accessory nutrient clearly different from the anti-scorbutic substance and from that other made so familiar by the story of beri-beri came later into knowledge. This is the so-called fat-soluble vitamine. It is made by the plant, is present universally in green vegetable tissues, and is in most seeds, but it does not necessarily accompany the vegetable oils and fats when these are expressed or extracted. The animal, however, happens to store this substance in association with its depôts of fat—hence its name. Grave errors in nutrition follow upon its absence from the diet, and this circumstance has added a greatly increased importance to the whole question of the national fat-supply. Once again we learn that something more than the gross amount of a foodstuff must be considered in evaluating its nutritional capacity. For the future we must apply a new criterion of value to fats.

I will not now discuss the relations of fat-soluble vitamine deficiency to disease, though the matter is one of profound and present interest. Many points are at issue, but intensive work is being done, and our knowledge will rapidly increase. In my belief the practical issues will ultimately be astonishing in their importance.

Pellagra.

Since your attention was for so long directed to the question of protein, I must, before closing, refer to the possibility that an ill-balanced protein supply may be a reason for failure in health. In this connexion we turn to pellagra. Of this disease much has been heard of late, and its interest was enhanced by its prevalence under the conditions of the war. The supposed evidence for an infective or toxic origin has gradually weakened, while that pointing to a dependence upon diet has recently become strong. Goldberger, who has studied it closely in America, considers that it follows upon the consumption of diets in which more than one deficiency, including constitutional faults in the protein eaten, contributes to the total result—a view which can, I think, be harmonised with all that we know about metabolism. But W. H. Wilson, of Cairo, holds that dependence upon proteins of "low biological value"—ill-balanced proteins—is the main determinant. The evidence, you should understand, is yet far from complete, but two striking experiences may be mentioned. Wilson found pellagra rife in a camp of Armenian refugees, and noted that their diet, though sufficient in calorie value, contained proteins of low nutritive value only. At his suggestion this error was corrected and, without other changes in treatment, pellagra thereupon disappeared.[7]

---

[5] Proc. Roy. Soc. Med., 1920, xiii. (War Section), 51.

[6] Cf. Karl Pearson: Grammar of Science, second edition, p. 113.

Goldberger[8] has studied the question in a large asylum. In all its wards were cases of pellagra among both coloured and white patients. The only change he introduced was an improvement in the quality of the proteins of the food. But with this pellagra disappeared from his wards, though persisting in other wards where the change was not made. When from the latter pellagrins were transferred to Goldberger's wards his treatment was equally successful. There are probably other factors in the ætiology of pellagra, but its behaviour strengthens much other evidence which shows that the recognition of specificity in proteins is of more than academic importance. If the application of all these considerations to practical medicine bore only upon the production of actual disease they would have far less importance than, in my belief, is actually attached to them. A deficiency which when extreme produces actual disease will, almost certainly, when less extreme involve some failure in health.

I was once greatly impressed with happenings at a large preparatory school. The boys were mostly quite young. Their health during a winter term was vaguely unsatisfactory. The majority became listless; the standard both of work and play fell much below normal, and various forms of minor trouble were reported. Explanation seemed difficult. The drains were inspected, throats were swabbed, but nothing came to light. The diet was considered, but was found to be ample and of good quality. Finally, however, it was noticed that being a winter term the kitchen supplied almost nothing in the way of uncooked food; and relatively little of green vegetables or fruit, whether cooked or otherwise. This by itself would perhaps have mattered little; but during that term it happened that the village shop where the boys had been wont to spend a portion of their pocket money upon fruit was closed. When this was realised, and a little fresh fruit supplied, all trouble disappeared. There was at no time scurvy in the technical sense, but the school was assuredly *feeling a lack of the anti-scorbutic vitamine.*

If the practitioner, when considering whether diet may not be the cause of a case of ill-health, has in his mind the idea of specific deficiencies he will no longer reject the possibility when general underfeeding or ill *digestion alone* have been excluded. Realising that details must be considered, he will, in my opinion, be able to ascribe more to diet than hitherto, and at the same time extend his list of cases diagnosed. Mostly will this prove true when the patients are young.

If we prove justified in ascribing to nutritional errors more—even a little more—of failure of health and development in children, the circumstance will surely be a happy one. A little more of evil becomes referable to nurture instead of *to nature*; *to environment* instead of to inheritance; and, therefore, to the remediable instead of to the irremediable.

Conclusion.

Before closing my remarks I would like to say why I think the coming year will stand out in the history of *the developments which have been before you. No* secret will be betrayed by reference to what may prove a classical experiment: An experiment on human material, involving a comparison; yet wholly legitimate, because each of the policies which will be compared possesses the complete faith of those who will carry it out.

Under the scientific auspices of the Lister Institute and the Medical Research Council Dr. Harriette Chick and Dr. Elsie Dalyell, with a proper staff, are in Vienna, in the home of the Nem System. They are there to apply the newer principles to the nutrition of children in the wards of von Pirquet. In adjacent wards the Nem System will go on undisturbed. A real comparison will therefore be made. The enterprise is unique in its occasion, in its international character, and in the high qualifications of those who are to conduct it.

I venture on no prophecy as to the outcome, but I cannot help holding very firmly to the faith that Vienna will show how important to practical medicine are recent advances in the science of nutrition.

An Address

ON THE

PSYCHOLOGY OF ANÆSTHESIA.

Read before the Section of Anæsthetics of the Royal Society of Medicine

BY DUDLEY WILMOT BUXTON, M.D., B.S. LOND., M.R.C.P. LOND.,

CONSULTING ANÆSTHETIST TO UNIVERSITY COLLEGE HOSPITAL, THE HOSPITAL FOR PARALYSIS, QUEEN-SQUARE, ETC.

SOME explanation of the title of this paper seems desirable. Psychology is defined in the dictionaries as "the science of the phenomena of mind—mental science," but as under anæsthesia the functions of the mind are commonly held to be out of action it may appear inaccurate to formulate any connexion between the causation of the phenomena evinced by an individual under anæsthesia and psychology. I hope, however, to be able to show that there are quasi-mental phenomena during narcosis. Any alternative title would have necessitated the employment of a long and cumbersome explanatory phrase.

In his "Metaphysics" Sir William Hamilton defined psychology as "*the Philosophy of the Human Mind, strictly* so denominated is the science conversant about the phenomena or modification, or states of the mind, or Conscious subject, or Soul, or Spirit, or Self, or Ego." This extends the limits of psychology, and since the days of Hamilton biology has enabled us to accept a still wider concept of the sphere of psychology, for we now accept that science as capable of enfolding experimental investigations of phenomena which cannot in any sense be regarded as confined to *the action of the conscious mind.* The materialistic school accept psychology as a science dealing with the phenomena of the conscious being even although the Psyche is not in its view the Soul, or the Spirit, or indeed the Self or Ego taken as an individual entity out of relation to its phylogenetic origin. Dr. G. W. Crile, whose work *stands out* as a bold attempt to explain the phenomena of man's life by a study of the cellular changes observable in his brain after physical work—and physical work is in his view the objective evidence of stimulation of his brain matter—offers us a definition of psychology. He suggests that it is "a science of man's activities as determined by the environmental stimuli of his phylogeny and of his ontogeny." Such activities may be of the conscious or the subconscious mind.

Anæsthesia and the Abolition of Consciousness.

I suggest that we are justified in believing that the older views about the mentality of a person under anæsthesia are inaccurate and need modification. Indeed, I submit that we are *justified in postulating* that the abolition of consciousness *does not necessarily* predicate the smothering of all emanations from the higher brain centres, although such emanations differ both in kind and degree *with the depth of* the narcosis.

The old concept of anæsthesia and deep narcosis was that the individual in such a state was practically in the condition of a frog whose brain has been destroyed. It was taught that the animal functions necessary for the persistence of life were preserved, but they were no longer subject to modification or under any sort of control by the brain centres. This view, I submit, we must now throw over.

Many of the avenues which bring an individual into communication with his enviroment are certainly closed under anæsthesia, but how many I think we are at present unable to determine. The number of such closed doors, and the extent to which some of them may be left ajar, or opened under sufficient peripheral stimulation, is also matter for investigation. But supposing that the anæsthetised person is cut off from any relation with other individuals we have no evidence that he does not retain some degree of consciousness, or if one may be permitted the term, of subconsciousness. In such a state, although he cannot functionate as an intelligent being or have any inclination so to do, he may, under appropriate external stimuli or auto-stimulation, bring about effects which influence his personal welfare. The extent of our adoption of this view is a severely practical problem the solution of which cannot fail to assist us in our everyday work as anæsthetists.

The commonly accepted tests of consciousness are only reliable in so far as they give evidence of the abrogation of certain reflexes; they give us no information concerning the persistence or absence of subconsciousness, if such subconsciousness does, indeed, survive the intensive application of anæsthetics.

If I may interpolate a suggestion at this point which the use of the phrase "the intensive application of anæsthetics" invites, it may shed a little light upon the question of the persistence of subconsciousness.

Differing Intensity of Action of Anæsthetics.

The various anæsthetics in use differ in the degree or intensity in which they act. Accepting the usual abolition of reflexes as criteria of anæsthesia we recognise that Snow's third degree of narcosis—surgical anæsthesia—is a profounder condition of unconsciousness under chloroform than under ether, demanding a longer period of recovery of mental balance, and ether in turn produces a deeper state than nitrous oxide gas, although to outward seeming each has rendered the patient merely "anæsthetic." It may be a question of the depth of the penetration of the drug into the protoplasm of the cells of the nervous system. Even if this is a mere matter of physical and chemical interaction it is not extravagant to suggest that anæsthesia may be caused before the entire abrogation of subconsciousness.

Unconscious Cerebration or "Awareness."

Carpenter, in his "Mental Physiology," gives some extremely interesting and in this connexion important instances of what he termed "unconscious cerebration." The individual's ego functionated with his higher cerebral centres but did so without being aware of such activity. The usual effect of ratiocination was brought about, but ratiocination was non-existent.

I am fully alive to the fact that psychologists may decline to accept my connotation of the terms subconscious and unconscious cerebration, and I readily admit the use of them is open to grave adverse criticism; still I can discover no better words and trust that I may be forgiven, and—what is more important—that my meaning may be clear. As to the proofs that such residuum of consciousness persists under certain degrees of narcosis—anæsthesia, semi-anæsthesia, and so on—such proofs are only presumptive and I propose to deal with them immediately.

The trend of modern thought is to recognise that the state usually designated consciousness is really an epiphenomenon, that throughout the nervous system there exists an "awareness" which in the higher centres we call consciousness, but which also exists below these centres. It is revealed in the spinal cord by the reflexes with which we are familiar. Some years ago I published the results of experiments which showed that under nitrous oxide gas ankle clonus could be elicited. The patient was unconscious, but below a certain level his awareness was actively present, and being no longer controlled the reflex developed. So it is fair to assume that in certain persons whose higher controls are readily put out of action by anæsthetics, there arise phenomena due to the "awareness" of the centres, even when consciousness is temporarily lost. These phenomena occur during anæsthetisation of neuropaths, neurasthenics, and so on. The truth of these statements has been shown by many cases of cord and brain injury met with in wounded soldiers, although, so far I know, their relation to the problems of anæsthesia has not been recognised. The "awareness" of the centres reaches certain levels and the phenomena vary with the levels reached. If, as I maintain, we are able to alter the level of consciousness or "awareness" by anæsthetics, we bring about states similar to those arising through trauma affecting the higher or lower centres. The "awareness" may and does persist in the lower centres, while consciousness, the "awareness" of the brain, is lessened or lost. I am indebted to Dr. Henry Head for the term "awareness," which seems more suitable than the expressions "subconsciousness," "liminal state," and "unconscious cerebration." We need a word to express the residual state of activity of the parts of the nervous system when gross consciousness is abrogated or lost.

Nerve Storms during Anæsthesia.

Crile would have us believe that a physical impress is made on the brain cells by the emotions, notably by fear, the emotion with which our work brings us into closest contact.

In his "Origin and Nature of the Emotions" he discusses these matters and compares the effects of emotions to those of trauma under anæsthesia. He writes: "Although no pain is felt in operations under inhalation anæsthesia, *the nerve impulses excited by a surgical operation still reach the brain.*" In this statement he is not in accord with the findings of Longet or of Waller based upon their classical experiments on the spinal nerves, since these observers recognised that anæsthetics act directly upon the nerves as well as upon the nerve centres. We may now consider these facts, which are suggestive, even if they do not amount to proof.

My experience has forced upon me the need for an explanation of the nerve storms and bizarre phenomena arising during induction and maintenance of anæsthesia in certain types of subject. For many years I had remarked that soldiers, whether officers or privates, were not only very difficult to anæsthetise, but were prone to evince unusual and often dangerous phenomena, both in "going off" and throughout the operation. Similarly I found neuropaths, highly nervous persons and that large class of patients whom we group somewhat unsatisfactorily in the category of neurasthenics, with babies and alcoholics, resembled soldiers in being "bad patients." What struck me most was that persons possessing an unstable nervous system evidenced by curious and troublesome nerve symptoms, were liable, even although no definite disease of their central nervous centres existed, to unusual phenomena both during induction and maintenance of anæsthesia. They appeared to project their conscious nerve dyscrasia into the period of anæsthesia, so that nerve storms arose interfering with respiration, circulation, and other functions. What I wish to indicate is that in these cases temperamental peculiarities became manifest even when consciousness was absent. One is tempted to add, even though consciousness was absent, a residual subconsciousness persisted; the higher centres, cut off from the external world by the anæsthetic, remained in function and dominated those centres which were necessarily still active for the maintenance of life. Possibly such nerve activity is of a quasi-defensive character or arises through abolition of repression of phylogenic activities. Psycho-analysis, to which I shall return, may help us to explain these phenomena.

In the categories of babies and alcoholics we have other factors with which to deal. In the first class there exists a notably unstable nerve-centre equilibrium and a narrow margin between the zone of anæsthesia and the spread of narcosis to the degree of overdosing of the whole nervous system. Babies and young children are dominated by their phylogeny, their ontogeny being as yet hardly developed.

I was at one time tempted to believe that alcoholics were bad subjects because their tissues were more or less damaged; this, however, is a half-truth, and does not explain why in their case the unusual phenomena of anæsthesia resemble in a remarkable degree those which emerge in the case of neuropaths and neurasthenics. I think I overlooked the fact that alcoholismus is a *disease grafted* upon an individual whose nervous system is on the borderland of abnormality; possibly others have made the same mistake. If this be a true deduction we have in their case to deal with patients who have a nervous system obnoxious to such drugs as anæsthetics and have lost their normal recuperative and resistive powers owing to chronic toxæmia. It is an interesting fact that alcoholics are extremely prone, even under profound anæsthesia, to move, to phonate, and to exhibit symptoms which may well be defensive or a revival of repressed phylogenic activities.

Observations on Soldiers.

These observations were made by one anæsthetist and may be open to criticism on that score, but they fall into line with those of other workers who anæsthetised many soldiers during the war and placed their experiences on record.

In the first place it has to be remembered that the armies were composed of many different types of men, alike only in being below middle age, who were, although physically fit often subjects of some nervous disability. We are told that one man who had had two attacks of insanity was passed a having "a slight defect but not enough for rejection." My experience indicates that most of the men, whether really fit or suffering from nervous inefficiency, were "bad subjects." They took a great quantity of the anæsthetic before losing consciousness, were prone to struggle, to fight, to be restless, even after the ocular reflexes were in abeyance, and were very liable to respiratory and circulatory crises even when there was no more than the usual degree of trauma. Unlike the poorly nourished neuropath, who often evinces some untoward symptoms following the anæsthetic, they usually recovered consciousness normally. Some, however, passed through a stage of delirium resembling mania, and showed no further unusual after-effects. Perhaps I should modify this statement and divide the new army men into two classes—those who resembled the units of the old army in being physically fit and possessing good health, and those who were rendered "fit" by an intensive training. This latter type often showed severe after-effects.

Anæsthesia and Psychoses.

We learn[1] that whereas no new psychoses were developed as a result of war stress (Weyganat), war excursions and alarums were liable to fan into flame any latent predisposition to nervous disease. Psychoses we recognise as arising through toxæmic conditions or from mental conflict (psychogenic), and whatever the origin of the state there can be no doubt that those who are the subject of some psychosis develop unusual phenomena when given an anæsthetic. We owe to the workers in psycho-analysis the knowledge that our mentality is a complex of derived—that is, phylogenic—instincts and ontogenic or individual traits. The former are repressed in normal civilisation, but during war the primitive animal instincts escape; the fighter is no longer his former self as he was in civil life. A like change is engendered and favoured by acute illness, severe trauma, especially that of the head or spine, since these conditions, together with the unwise use of alcohol, cause loss of the habitual inhibition of the savage instincts of mankind. Another point of some importance is one noted by Read, "that the necessary curtailment of free thought and action involved in army discipline naturally leads to much repression." This repression at length calls for a vent for the lower instincts and an escape into the unbridled licence of savagery. Cannon has shown that intense emotions provoke adrenalism, and we are probably correct in believing that the secretions of the ductless glands other than the adrenals are also increased by similar stimulation. The soldier about to take an anæsthetic is usually under the dominance of fear and of other emotions, and he exercises severe repression so long as his controlling centres remain in control of his actions. He no longer has the support of "the herd," but experiences an exaggerated fear of what is to happen to him and the necessity for self-protection. The effect of the anæsthetic is to destroy the systems of restraint and open the flood-gates of primitive instincts, which in this case seek to liberate him from those who hold him; he even endeavours to destroy the latter, since they are for the nonce his obvious enemies. As Dr. Ernest Jones has indicated,[2] the investigations of psycho-analysis have shown that the influence on conscious life of these impulses (primitive inherited instincts), which are in a repressed state in the unconscious mind, is of an unexpected importance, and, what is more, that the impulses themselves are indestructible. Moreover, the adrenalism to which reference was made above no doubt accounts for some of the abnormal states of the circulation so common in such cases.

We may sketch the mental picture in the mind of the fighter and recognise that it may provoke the outbursts of disconcerting activity under the anæsthetic. In some men it is the vivid recalling of recent experiences, in others the blurred impression of a phylogenic complex which carries the individual back to a primitive environment. Are we justified in believing that this is the explanation of abnormal phenomena which develop during anæsthesia in individuals of the classes we have considered? It may be objected that there is a gulf fixed between the mentality of the soldier and that of the civil neuropath, but such is not really the case. Similar results are reached, although by different routes. The berserker rage of the warrior and the perverted mind-state, conscious or subconscious, of the neuropath are one and the same departure from the normal, and as such cause similar phenomena under anæsthesia.

Dreams Occurring under Anæsthesia.

There is another and most interesting aspect of this question—the study of dreams which have occurred under anæsthesia and left a profound impression on the unconscious mind. The study of these dreams sheds some light upon the psychology of the state, and seems to support the contention that there is a period of liminal consciousness beyond that which passes into abeyance early in narcosis.

Dreams, common with every kind of general anæsthetic, are not always remembered. Patients will say that they had a "lovely" or a "dreadful" dream, but cannot recall it in detail. Many such dreams probably arise as the patient is resuming consciousness; if of a disagreeable character they are usually the result of some perception of pain due to the concluding steps of an operation or of "after pain." This is a common type with nitrous oxide gas inhalation, and has little significance for us in the present connexion. Pleasurable dreams fall into another category; they are worthy of close investigation, as are also the dreams often called "horrors," which leave an indelible impress upon the mind and may be recalled at wide intervals of time under subsequent anæsthetisations.

Among such dreams we can recognise types. The erotic type, not infrequent with nitrous oxide gas or ether, and less common with chloroform, can often be recognised by muscular movements which suggest orgasm. The patient, unconscious of his or her surroundings at the time they occur, is left somewhat exhausted, and in the case of women obviously disturbed if the anæsthesia has been brief and recollection of the erotic sensation is dimly present upon recovery. It is such dreams which form the basis of charges of assault often preferred in good faith against surgeon, dentist, or anæsthetist. I have been told repeatedly by men that they have had a "good time," meaning erotic dreams have lightened the tedium of anæsthesia. Those who enjoy the sensation of alcoholic exhilaration will say they have had a "splendid drunk," and their muscular movements during the stage of recovery suggest bacchanalian fancies and amatory hallucination.

Deeply Impressed Dreams.

I have met with different forms of dreams deeply impressed and either remembered or recalled. The importance of these is great.

A person will have a dream under an anæsthetic which is so vivid as to amount to a subconscious experience, as if it were an episode in another life. One recalls the case of John Addington Symonds. At the period of his mental storm and stress, I think when he was at Davos, his mind was perturbed by doubts as to the truth of revealed religion. Symonds was given an anæsthetic and under its influence he passed into what he describes as a kind of trance. The presence of the Almighty was revealed to him and the Voice said, "It is I whom you deny." One need not labour the story, it is one of the type of constructive dreams which are very vivid and persist. I had a patient who, like a character in George Du Maurier's novel "Peter Ibbetsen," "dreamed true." She told me that every time she inhaled nitrous oxide she dreamed of a friend, and felt as if she was in the society of this friend; she remembered what she had dreamed before, took up the thread of the narrative, and continued it in each successive dream. I regret I have lost touch with this patient and so am trusting to my memory concerning it and to a scant note made at the time when I was told the story. In another case the patient informed me that she always had "a delightful dream," which was repeated on each occasion when she took gas. The details she kept to herself.

In these dreams we find a persistent impression left upon the subconscious mind, capable of being revived under certain presumably similar conditions.

The best example of this I have met with was in a highly intellectual man, a teacher at one of the old universities, highly nervous and neurotic. He had to have all his teeth removed but could not face the ordeal. Finally, his sister, also an intellectual, who had been a patient of mine, suggested he should consult me. His history was typical of many such cases. In childhood he had been given an anæsthetic and had had an exceedingly bad time. The recollection of that experience was an abiding horror. When I saw him it was obvious that his condition was a serious one; he was being poisoned but he refused an anæsthetic and distrusted any local analgesia. Luckily his sister had impressed him with my ability to help him. He consented to be re-educated as regards the effects of nitrous oxide, provided I promised to desist from any administration when he felt the old horror was gripping him. By repeated administrations, at first brief and stopped before unconsciousness, I was able to build up his confidence and belief in the efficacy of the anæsthetic, and so to submerge the old associated horror beneath the new and agreeable sensation. Of course this case is an extreme one, but it is probable that many patients who exhibit maniacal fear—a very dangerous thing during induction of anæsthesia—do so as a result of the revival in their subconscious state of preceding, and possibly forgotten, experiences which have deeply scarred their subconscious mind.

I think these cases, especially those in which a dream is repeated in identical detail at wide intervals of time, indicate that in anæsthesia we are dealing not only with ordinary consciousness as tested by motor reflexes, but with the subconscious hidden mind, access to which is made possible again and again when the use of an anæsthetic is invoked on successive occasions. But some patients who long before taking an anæsthetic have lived abroad have during the induction period of anæsthesia commenced to speak in some native dialect, uttering phrases which had not passed their lips for years. Here we have no associative nexus between the anæsthetic and the harking back to the experiences of bygone years, but I think we have evidence of inhibiting the repression which the new conditions of life in England would naturally impose. Carried further, as it is in many persons, the removal of repression leads to furious struggling and protective efforts, as of one attempting to ward off the attacks of his enemies. In soldiers, as has been said, this is very common.

[2] War and Individual Psychology, Sociological Review, July, 1915.

The Problem of Prophylaxis.

How far anæsthetics can penetrate the veil of the unconscious mind and protect it from obnoxious impressions has yet to be determined. The power to do so is limited, I think, by the individual psyche.

In the classes to which I have particularly referred—those who are the subject of some psychosis, the neurotic, the neurasthenic, the toxæmic, and persons of a poorly developed and unstable nervous system in general—the anæsthetic awakens both phylogenic and ontogenic traits more readily than is the case with the stormless individual with an irreproachable central nervous system. In these classes we expect not only the muscular storms but look for interference with the controls of circulation and respiration with their associate and definite dangers. The establishment of prophylaxis in such persons becomes a practical problem, and one seeks for the assistance furnished by the experience of others. The subject which I have attempted to introduce to you is worthy of extensive study and research; we should receive valuable aid from the neurologist, and from the employment of psycho-analysis we may obtain light on our problem. There is danger that because we now get excellent results even with neuropaths we may relegate the study of psychology to the limbo of the unnecessary developments of thought. It must be noted that anæsthetists seldom have opportunities, unless they make them, of following up abnormal cases for months or for years; so they may miss the profound psychic developments which have their rise in an anæsthesia. We are not infrequently told that such and such a patient must not be given an anæsthetic because of a serious upset and prolonged illness which followed an operation under an anæsthetic which took place some years ago. Such a case is one for study, not one to be refused the benefit of general anæsthesia, since this form of narcosis is peculiarly useful in the case of psychoses and neuropaths. The study made, we should be prepared by knowledge, much of which has yet to be gathered, about the best form of anæsthesia and method of its production, with detailed attention to the patient's environment and preparation. This preparation should often be prolonged, and should be directed not only to the needs of the body, but also to those of the mind. To take a concrete example. Crile's "stealing of the thyroid" is accomplished by a method admirable in its conception since it deals with the patient's mental as well as his physical requirements. I have been greatly struck by a remark of the lady who appears to give many of this surgeon's anæsthetics. She insists that a definite and formal part of the induction scheme she pursues is re-assurance of the patient; the mind is supported, fears are banished, and a sense of well-being engendered by the determined efforts of the anæsthetist, while the anæsthetic is steadily given, and given without hurry or impatient intolerance of a nervous person's natural trepidation.

Dangers of Injudicious Administration.

How real is the danger of injudicious methods of administration and of a faulty choice of agents is shown by the following facts.

Sir George Savage has told me that patients who are or have been insane not infrequently develop mania after ether. I have known transient maniacal delirium to arise in patients who at the time of the induction were apparently sane, and have on subsequent occasions substituted chloroform given with oxygen in place of ether with satisfactory results. I am convinced that every ounce of ether saved by limiting the dose during maintenance of anæsthesia, after complete anæsthesia is obtained, is a step towards lessening post-anæsthetic mental disturbance.

I know of at least one case, and others have been noticed, in which acute mania lasting for some weeks has followed the operation of the radical cure of hernia undertaken under a local analgesic. The patient was a medical man of assured sanity, but I do not know whether he had any tendency to a psychosis.

When spinal anæsthesia is employed and no preliminary injections of alkaloids are given, and when a general anæsthetic is not adopted concurrently with the blocking of the spinal nerves, a high degree of psychic shock appears in many cases, the effects of which persist for a considerable time after the operation. This state seems to be in some ways analogous to the effect of a general anæsthetic given to the subject of a psychosis. In the one case the apprehensive centres are wholly unprotected from the perturbations of fear; in the other these centres appear ultimately to be thrown out of action. During the period of induction, however, they are not completely protected, and activate to the extent that they cause the phenomena of struggling, and that nerve storms arise which interfere with respiration, circulation, and the even process of induction.

Anæsthetisation of Psychopaths and Neuropaths.

At present we possess certain methods which my experience of their use extending over some years leads me to believe are satisfactory in cases of individuals who fall into the categories of psychopaths and neuropaths.

The use of alkaloids before inhalation or colonic etherisation is unquestionably valuable. There is a common, but I think mistaken, impression that morphine and atropine best subserve the ends in view. It is general experience that the dose of morphine usually given—namely, ⅙ gr. one hour before inhalation—is insufficient to produce the requisite drowsing of the patient, and so larger doses are ordered. This is certainly true in the case of soldiers. Now these large doses of morphine, even if they achieve their aim, exercise a very deleterious effect upon the nervous system and parese the respiratory centre to a dangerous extent. If, however, scopolamine is added to the morphine and atropine a more stuporous effect is arrived at without damaging the functions of respiration. It is true that scopolamine acts in some ways similarly to morphine, but we must remember that it belongs to the atropine group, and so while it drowses the senses it stimulates the respiratory centre. Drugs in combination act in some ways synergically; in others they are antagonistic, as in the case of atropine, morphine, and scopolamine. Another practical point is that we require the optimum effect of these drugs when the induction is commenced. If it comes on later it is a danger, and so at least an hour should elapse between the giving of the hypodermic and the administration of the anæsthetic. An equally important matter is that the patient should be ensured a good night's rest before the operation. The use of a hypnotic may be undesirable in some ways, but its benefit is great in others, the latter being, in my opinion, important. After this night's rest the patient should not be disturbed unless it is absolutely necessary to have enemata or be given indigestible beef-tea.

This, in brief, is the line of treatment I suggest; it will, no doubt, be modified, possibly with advantage, in the hands of others.

Conclusion.

Although this is not strictly a matter for the anæsthetist, it may be noted that gentle surgery protects the patient from reflex dangers, while some form of blocking the centripetal nerves by analgesics, as in Crile's anoci-association method, is probably a protection against some shock effects, although, of course, the latter cannot be entirely abrogated in abdominal or thoracic operations. Another practical point calls for mention. I, no doubt in common with other anæsthetists, have noticed that if the induction is performed hurriedly or without due attention to detail, and if the operation is commenced before absolute anæsthesia has been obtained for some minutes, the whole course of the latter proves unsatisfactory. Do what one may, it is marked by an uneven level of narcosis; vomiting or retching is constantly imminent, and disturbances, usually vagal in origin, are common. Throughout the anæsthesia anxiety and dissatisfaction obtain, and severe after-effects usually occur. I believe that this trouble arises through no initial and complete control having been obtained over the higher centres. Consciousness may eventually be lost, but the influence of the unconscious mind is aroused; for some reason, at the nature of which we can only guess, its effects persist and are hardly abrogated.

To recognise this state is to suggest its treatment, whether or no we admit its suggested causation.

ORAL SEPSIS,

WITH SPECIAL REFERENCE TO CHRONIC DENTAL APICAL INFECTION.[1]

By W. BERTRAM WATSON, M.D. LOND.,
VICE-PRESIDENT OF THE HARROGATE MEDICAL SOCIETY; HONORARY PHYSICIAN TO THE YORKSHIRE HOME FOR INCURABLE AND CHRONIC DISEASES

THE presence at this meeting of many of our colleagues of the dental profession is an indication that they, as ourselves, realise how essential it is for the well-being of our patients that there should be, in the future, a closer coöperation between the medical and dental professions than has hitherto prevailed. Now that there is conclusive evidence of the importance of oral sepsis as a causative factor in the production of many constitutional diseases, dental theory and practice have become of greater importance; and members of the medical profession will continue to welcome all the help in diagnosis and treatment which can be given by their dental colleagues.

In such societies as ours there is perhaps a tendency rather to present other peoples' views, drawn from medical literature, than to relate personal experiences. You will forgive me if I go to the other extreme, giving you some account of my successes and failures, and of the changes that have taken place in my views on the difficult question of oral sepsis during the 21 years of my professional life.

We have only to look at the medical and dental journals of England and America to see that the question of the influence of dental infection on the health of the individual and of the nation is one of the most discussed problems of the day, and a topic about which the intelligent laity are thinking as well as ourselves. My interest in the question of oral sepsis was first aroused when I was a clerk and house physician at St. Mary's Hospital in the late "nineties," as a result of the study of the writings of Dr. William Hunter, the pioneer in this field of research. As has always been the case with teachers preaching a new gospel, Hunter's message for a long time fell on deaf ears, but the great value of his work is now fully realised; and his writings on oral sepsis as a cause of disease are as well worthy of study to-day as when they were written 20 years ago.

For the past 18 years my work, as is the case with most of my hearers, has lain in the sphere of chronic disease. I do not think it is altogether a disadvantage that patients who are sent to us for treatment are under our care for a limited period of the year only. They come here from year to year, which enables us to review the position at regular intervals, the result being that progression and retrogression in morbid processes, success or failure in treatment, make a deeper impression. A further advantage which we enjoy in our work in Harrogate is that we have the opportunity of studying cases which have been treated by different methods, by different physicians, in different countries, and many lessons are to be learnt from patients themselves.

Association of Oral Sepsis and Constitutional Conditions.

I wish now to quote a few brief notes of several cases illustrative of the association between oral sepsis and constitutional conditions. I had no difficulty in laying my hands upon the notes, because all these cases made a deep impression, standing out as peaks in my clinical experience.

CASE 1.—A male, aged 26, with a history of acute pain for three months in the metacarpo-phalangeal joint of right index finger. He was of good build and physique, led a healthy outdoor life, and had never known a day's illness. He was unable to write save for a short time only, and when he came to see me had his hand on a splint. The affected joint showed all the clinical signs of inflammation; no evidence of involvement of any other joint. Mouth appeared healthy, but the dental surgeon reported presence of one devitalised tooth. On my advice this was removed; within three days all inflammatory symptoms had disappeared from the joint. I saw nothing of this patient for 12 months; he then returned with precisely the same signs and symptoms in the same joint. Removal of a second devitalised tooth acted in the same way as on the first occasion, and I heard later from the patient that he was quite free from all trouble.

CASE 2.—A male, aged 45, with loss of power in upper extremities, chiefly in the hands. He had in both arms boring pains, which became worse at night, and at intervals sensory disturbances, particularly "pins and needles," in one or both hands. This nerve disturbance had been attributed to glycosuria from which he had suffered for some years. He was a debilitated subject, had worked hard in a City office, and looked and felt ill. Examination of mouth revealed the presence of a number of septic stumps, and marked gingivitis. I advised clearance of the mouth; within a few weeks pain and weakness in the arms had disappeared; further, there was a surprising reduction in the glycosuria—an observation which has stood me in good stead many times since.

CASE 3.—A female, aged 46, had enjoyed good health all her life save for present subacute rheumatism, from which she had suffered for nine months. The greater part of the time she had been confined to her bed; nightly temperature between 99°-100° F., pulse-rate 100-110. Began with pain in muscles of upper extremities; joints of both arms and legs then became involved. Prolonged fever, loss of sleep, and pain was beginning to tell on patient; heart muscle showed signs of enfeeblement. Severe gingivitis present round six or eight stumps, with which she parted reluctantly. Within 48 hours temperature and pulse-rate became normal; within a week patient was quite free from pain, and in a comparatively short time she was able to return home in an ordinary compartment instead of by invalid saloon, in which she came. A year later this patient again came under my care, having remained quite well for six months; since then a recurrence of pain and swelling of knee-joints. The mouth was completely cleared on this occasion. Patient wrote later, giving a good report of her condition.

CASE 4.—A male, aged 68, with an anomalous skin eruption which had been present for three weeks. Numerous small vesicles and pustules on body, neck, face, and arms, and raised red blotches on hands and other parts of body. Repeated crops of ulcers on tongue and lips prevented his taking solid food for three weeks During previous summer he had been troubled with gums and throat, for which he had undergone a course of vaccine therapy. Gums, teeth, tongue, fauces, and pharynx were acutely inflamed: a well-marked example of profound and generalised oral sepsis. Blood picture was one of pernicious anæmia, although degree of anæmia was not extreme. Further blood examination made at an interval of 10 days showed a reduction of red blood cells from 3,400,000 to 2,800,000. Culture from gums gave an abundant growth of streptococci; urine culturally negative, and incubation of a swab on agar from a pustule for 48 hours gave no result. Two or three days after his arrival the patient became febrile, and in spite of energetic local antiseptic treatment he died within a month from acute septicæmia. I believe it to be a well-recognised clinical fact that there is a special malignity in streptococcal infections involving bony cavities and bone substance.

Further Conditions found in Association with Oral Sepsis.

If time permitted I could give you notes of many other cases that have passed through my hands—some complete successes, others partial, through recognition of oral sepsis as the causative factor of the condition. The business man in the "forties," whose only complaint is that he does not feel fit, is tired after his game of golf, and has lost the sense of physical well-being—dyspeptics of various types, and in this last group we have perhaps allowed our minds to dwell on the element of unsatisfactory mastication and not sufficiently on the toxæmic element. I believe ophthalmologists will tell us what my limited experience has taught me, that in very many ocular conditions—e.g., cases of iritis, iridocyclitis, and retrobulbar optic neuritis—the cause is to be found in the mouth, and the cure is the work of the dental surgeon. This is not to be wondered at when we consider the close association regarding blood-supply between the teeth of the upper jaw and of the structures in the orbit via the pterygoid plexus.

I have quoted one case of acute septicæmia, and could quote many others of less important pyogenic infections due to oral sepsis—e.g., cases of recurrent boils and abscesses. From the successes which I have achieved in several cases of intractable urticaria I am sure it is wise to eliminate the possibility of dental infection in this condition. Fibrositis, so prevalent that we are perhaps entitled to look upon it as a British disease, is not entirely due to the dampness and chilliness of our sea-girt isles, but is oftentimes due to a toxæmia from the same source. Shall we not have to modify our views to explain the high incidence of another peculiarly British institution—acute and chronic gout—recognising that we must reckon with a mild degree of sepsis as, at any rate, a factor? A number of writers in the medical press, particularly in America, have drawn attention recently to the rôle of oral sepsis in *hyperthyroidism*. I have recently had under my care a lady suffering from this condition in its early stages, for whom I thought of prescribing a course of radiotherapy, but after oral care she improved so rapidly that I have reason to believe that no further treatment will be necessary.

---

[1] Being the opening paper read at a discussion at the Harrogate Medical Society, Nov. 18th, 1920.

So far I have spoken of successes, complete and partial, but I have to record many failures. A number of people are to-day either wholly or partially edentulous on my advice, with no apparent advantage; and how many others there are in the same condition who tell the same dismal story after following the advice given to them by other physicians. There is, however, another side to the picture, as I have on several occasions, as a result of the subsequent history, had to regret not having advised radical treatment in the first instance; a case to illustrate this I purpose quoting shortly.

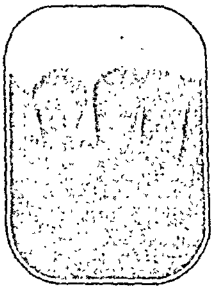

FIG. 1.—Normal teeth.

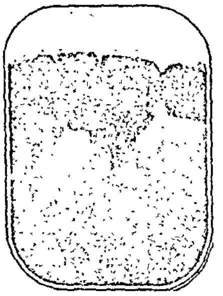

FIG. 2.—Bridge work and infected roots.

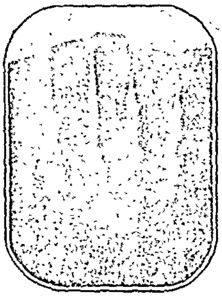

FIG. 3—Large granuloma at the root of lower incisor tooth, associated with pyorrhœa and marked alveolar absorption in the incisor area.

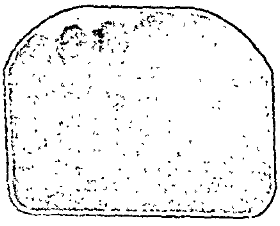

FIG. 4.—Lower molar tooth showing typical granuloma at each root.

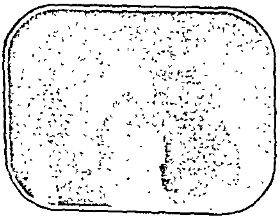

FIG. 5.—Gross infection around the roots of teeth.

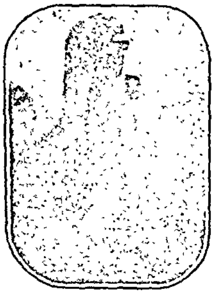

FIG. 6.—Gross infection around the roots of teeth.

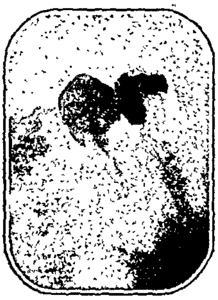

FIG. 7.—Granuloma at the root of tooth with filled dental canal.

Chronic Focal Apical Infection.

It is not my intention, however, to roam over the entire field of oral sepsis, but to draw your particular attention to one special part of the problem, that of chronic focal apical infection. The hypothesis on which I worked till a few months ago was that systemic infection from oral sepsis was chiefly due to the swallowing of countless milliards of pyogenic organisms. Eventually the time arrived, possibly on account of an enhanced dosage, or to diminished resistance on the part of the gastric secretions, when the bactericidal action of the gastric juice became inadequate, and so live pyogenic organisms found a foothold in the gastro-intestinal mucosa. My view was that in those cases in which satisfactory results did not follow oral treatment the probable explanation was that the stable door had been shut after the horse had gone, that the *Streptococcus oris* had taken up its abode in the colon, its cultural characteristics no doubt changing in course of time through correspondence with its new environment.

I fully recognised the possibility of a generalised infection from the buccal cavity, but felt that this did not altogether "fill the bill." The first case which I have quoted did not satisfactorily fit in with this conception of the morbid pathological process, and I now purpose giving some details of a further case which to me was very instructive, and in which I was sorry that radical treatment had not been adopted at the commencement.

CASE 5.—In the summer of 1915 a lady in the late twenties consulted me on account of considerable swelling of three of her finger-joints, probably periarticular, and possibly with fluid present. For some months she had been subject at times to swellings, accompanied with pain in finger- and toe-joints. Her dental surgeon and physician in London were in agreement that the condition of her mouth was perfect. I examined her mouth carefully and found everything satisfactory. She was proud of her teeth, had paid unusual attention to the question of oral hygiene, and had never had toothache. Tonsils and naso-pharynx healthy, general health and personal medical history good. On the three or four occasions that I saw her I noted that she had a slight rise in temperature—99° to 99·5°—with quickened pulse, which naturally made one search the more diligently for a focal infection. On my advice she again saw her dental surgeon and took a further opinion, which again corroborated our findings. In the summer of 1916 I saw her again; her general health was becoming impaired; the inflammatory changes had progressed in joints originally affected, and fresh joints had become involved. She sought further advice from a third dental surgeon, who cleared the mouth, and later she had a course of treatment with an autogenous streptococcal vaccine. For a few weeks after this operative procedure the patient was gravely ill, since which time no fresh joint lesions have appeared.

This case illustrates the danger which is run by undertaking the surgical treatment of too many foci at the same time. Had the teeth been removed gradually, absorption of toxic material would have been spread over a longer period, with much less risk of constitutional disturbance.

Dental Radiography.

Last winter I visited some of the great clinics and a number of the smaller hospitals in the United States of America. I was much impressed with the position that dental radiography occupies in that great country. Some of the most stimulating hours of my life were spent at Rochester, Minnesota, in the society of Dr. Charles Mayo. He took me first to the dental radiographic department of the Mayo Clinic; there I found that a radiographic examination of the teeth formed part of the routine examination of the patient. In the past few years I had occasionally seen dental radiograms, but must confess I could make but little of them; nor did I receive much enlightenment regarding them from my dental surgeon colleagues. After seeing a few hundreds in America, I found no difficulty in interpretation, and began to realise their great value for diagnostic purposes. My attention was particularly directed to the question of chronic apical infection from a radiographic standpoint. As a result of the infective process there is a destruction of cancellous bone tissue at the site of the mischief, which is indicated in the accompanying radiograms by a light area. I learnt that if such a light area be discovered in the alveolar process at the apex of a devitalised tooth or about a root, it was possible on radiographic evidence alone to make the positive diagnosis of chronic apical infection; and, further, that with the elimination of the inflammatory process the cancellous tissue resumed its normal character and appearance.

Dr. Charles Mayo arranged for me to have an interview with Professor E. C. Rosenow, to whom the medical profession owes a debt of gratitude for much original work, by no means the least important of which has been his bacteriological studies of dental infection. He demonstrated to me his methods of cultivation, also many micro-photographs of granulomata near the apices of extracted teeth, showing bacteria lying in close proximity to blood-vessels. From a study of these it was easy to see that bacteria have no difficulty in passing straight into the blood or lymph streams, and that, in consequence, chronic apical infection from a theoretical standpoint is the most dangerous of all forms of oral sepsis. I had been mistaken in my view that the harm lies in the swallowing of pyogenic organisms, and learnt that the chief danger arises from direct absorption into the blood stream of bacteria and their toxins. Moreover, this menace is the more serious because it usually gives rise to no symptoms and no pus formation. I now began to see daylight. Had the patient whose case I last quoted been radiographed in the first instance, a method of investigation of which neither her dental surgeons nor I had availed ourselves, a correct diagnosis of chronic apical infection could have been made, and I think I am justified in saying that with proper treatment her joint symptoms would soon have disappeared, before grave organic change had supervened.

Elective Localisation of Bacteria.

I can do no more than refer to Rosenow's work on the elective localisation of bacteria. I venture to quote one of his cases dealing as it does with a condition with which we have to deal so frequently. A middle-aged physician had repeated attacks of pain in the right gluteus maximus muscle and stiffness of the muscles of the back. A granuloma was found over the apex of the root of an extracted tooth, which on cultivation gave a short-chained green-producing streptococcus, a few hæmolytic streptococci, and a moderate number of slightly hæmolysing streptococci. A rabbit was injected intravenously with the growth, and at the necropsy the right gluteus maximus muscle was found to be hæmorrhagic, and there were a moderate number of lesions in the more tendinous portions of the muscles throughout the body. Rosenow quotes, among others, cases of myelitis, iritis, multiple neuritis, and arthritis, which pathological changes he has been successful in reproducing in rabbits by intravenous injections of cultures from granulomata found at the apices of teeth in patients suffering from these conditions.

It is obvious that our only hope for a really successful issue, in dealing with cases of systemic infection from oral sepsis, is to attack at the very beginning of the morbid process. To be logical, one should first consider the problem as to how apical infection takes place, whether via the periodontal membrane, the dental pulp, or the blood stream; but the consideration of the ætiology and prevention of the condition is one for the dental pathologist, and does not fall within the scope of this paper.

Is Simple Extraction Adequate?

With a patient suffering from a systemic disease in which an infection at the apex of one or more teeth is discovered, What is the correct treatment from a dental surgical standpoint? Rosenow teaches that simple extraction is not adequate, and that persons who have had all their teeth extracted may still harbour localised areas of infection in the jaws. May not this be the explanation of some of the failures to which I have already referred, the apical or periodontal infection having been left or only partially removed? I am, of course, referring to cases in which there is no other manifest focus of infection in the tonsils, naso-pharynx, accessory sinuses, &c.; and let me add that it is rare to find infected tonsils without infected teeth being present at the same time. If the infinite capacity for taking pains be the correct criterion, my friend, Dr. B. S. Gardner, who is in charge of the dental department at the Mayo clinic, is a genius, because he takes no chance of not completely eliminating apical infections. It was my privilege to see him operate on a number of cases, all performed under conductive anæsthesia, which appeared to me to be most satisfactory alike to patient and surgeon. His practice in some cases is to make a half-inch round incision to cut loose a flap of the soft tissues, and so expose the alveolar plate which forms the labial wall of the socket of the affected tooth. A window is then made by removing the alveolar plate to uncover the infected area. The tooth is then extracted, and granulation tissue removed with a curette until healthy bone is visible on all sides. After the cavity has been washed out with an antiseptic solution the flap is drawn down and sewn into position carefully with horsehair stitches.

Analysis of Seventy Cases Investigated by Means of Dental Radiography.

During the past six months I have utilised dental radiography in the investigation of 70 cases in which the consideration of the personal history and clinical findings led me to believe that help in diagnosis might be forthcoming. The greater proportion of these, 31, were cases of fibrositis: in 23, definite apical infection was revealed, and of the 23, in 13, the condition was associated with rarefying osteitis in the neighbouring alveolus, 2 showed rarefying osteitis only, leaving 6 in which no changes were observable on the dental films. Six out of 10 cases of neuritis showed apical infection, 2 of these with rarefying osteitis in addition, and 1 with rarefying osteitis alone. Of 7 cases of arthritis 4 showed apical infection alone, and 2 apical infection with rarefying osteitis. In 13 patients suffering from general ill-health, with ill-defined dyspepsia, there was radiographic evidence of dental trouble in all—7 had apical infection alone, 2 apical infection and rarefying osteitis, and 4 rarefying osteitis alone. In one case of kerato-cyclitis there was gross apical infection; in one case of alopecia, in which a dermatologist suspected the presence of a focal infection, radiography revealed some buried roots with granulomata; in one case of urticaria giganta gross apical infection was revealed, involving several teeth, together with rarefying osteitis. One case of trigeminal neuralgia, probably due to the presence of a buried root in the upper jaw, was undiagnosable save by radiography. One case of persistent pyrexia disappeared after the removal of infected teeth and tonsils. In 3 cases of general toxæmia of unknown origin and in 2 unclassified cases of no importance there was gross apical infection.

I now purpose giving a few details of 8 of this series of 70 cases which received dental surgical treatment while under my care.

CASE 6.—A young man suffering from neuritis of some months' standing, involving left upper extremity, had complete relief from pain three or four days after removal of offending teeth, with curettage of sockets. Radiographic diagnosis—apical granuloma.

CASE 7.—A male, aged 59, with fibrositis, chiefly confined to cervical and lumbar muscles, had suffered pain in consequence for six months. Nodules to be felt in affected muscles; evidence of synovial change in both shoulder-joints. Radiographic examination revealed gross apical infection of second right incisor and left bicuspid in the upper jaw, no pyorrhœa being present. Cultural examination of an extracted tooth yielded a pure growth of a hæmolytic streptococcus, from which an autogenous vaccine was prepared.

CASE 8.—A female, aged 34, with history of two attacks of rheumatic fever at ages of 8 and 28. Systolic bruits heard at both the mitral and aortic orifices, but no cardiac symptoms. For the past two years she had complained of muscular pains. Visible portion of teeth appeared sound; slight apical infection reported at apex of one tooth in upper jaw, and a large infection at apex of a second tooth in lower jaw; no pyorrhœa. Cultural examination of extracted teeth gave a pure luxuriant growth of a hæmolytic streptococcus; an autogenous vaccine was administered, and I hear she is now quite free from her muscular pains.

CASE 9.—A male, aged 40, who had complained of gastric discomfort, general ill-health, and slackness for two or three years; granulomata discovered around apices of most of his teeth. I advised complete extraction with curettage of sockets; notwithstanding his edentulous condition gastric symptoms speedily disappeared, with marked improvement in general health and increase in body-weight.

CASE 10.—A female, aged 56, had suffered for many years from repeated attacks of kerato-cyclitis. On the advice of an oculist she had seen her dental surgeon on many occasions, but he had always reported that her mouth was above suspicion. Apical infection was present at root of one tooth; the socket was opened by the alveolar route already described. Granulomatous material was removed, which bacteriologically after 48 hours gave a free growth of a Gram-positive diplococcus.

CASE 11.—A male, aged 34, gave in May, 1920, a history of pain in his feet for some weeks in 1917 and at intervals since. Since November, 1919, he had suffered from severe pain in both hands and feet; poor general health obvious. Fusiform swellings of interphalangeal joints of hands feet puffy clinically the picture was one of the œdematous type of early arthritis. Radiographic examination of right hand and foot showed inflammatory changes at present mainly confined to soft parts—i.e., periarticular; but there was evidence of wasting of bone in neighbourhood of articular surfaces. Visible portions of teeth appeared healthy, but by radiographic observation large granulomata seen at roots of a lower left molar, with absorption of root apices (vide Fig. 4). On digital pressure of tonsils yellow, offensive concretions were extruded. Tonsils were enucleated and the offending tooth extracted with curettage of socket. Tonsils on external examination showed numerous follicles, and on section pockets containing greenish pus. On cultural examination of tonsils a pure growth of a short-chained streptococcus was obtained; and cultural examination of tooth gave a pure growth of same organism. In a recent letter from his doctor I hear there is considerable improvement in general health, the weight having increased 15 lb. He says: "The feet are much better, and he walks quite decently now. The fingers are better, but still far from normal; the thickening over the terminal inter-phalangeal joints has gone, but the first inter-phalangeal joint, especially the first right finger, is very pronounced."

CASE 12.—A male, aged 42, gave in April, 1920, a history of general ill-health since 1915, and of a severe and prolonged attack of iridocyclitis in 1919. During this attack, a streptococcus was isolated from the urine, and a vaccine prepared from this source had proved of service. Mouth appeared healthy; but in upper jaw there was evidence of gross apical infection involving four teeth. Cultural examination of these teeth gave a luxuriant growth of a streptococcus, and a course of vaccine therapy, following removal of the septic foci, had most beneficial results.

CASE 13.—A male, aged 53, at present under my care, first consulted me five years ago on account of fibrositis, which I considered at that time was probably traumatic in origin. I saw him again in June, 1920; he gave a history of good health in intervening period. Nine weeks previously a window came down on his fingers and tore off the nails, since when he had had "rheumatic" pains in upper and lower extremities and lumbar area. General health was good; he took a good deal of exercise notwithstanding his muscular discomfort. There was much gold crown and bridge work in his mouth, and radiographic examination showed gross infection at the apices of four teeth. All forms of bath treatment exaggerated the symptoms, which gradually became more severe, finally confining him to bed, and necessitating the exhibition of opiates to relieve. He came under my care a month ago, and it was evident that there had been deterioration in his general health. Blood examination showed marked secondary anæmia, the hæmoglobin being 43 per cent only, but no evidence of pernicious anæmia. Wassermann reaction, negative. Blood culture, sterile. Cultural examination of the urine gave a short non-hæmolytic streptococcus. I advised removal of the four infected teeth one at a time, followed by curettage. After each extraction patient was ill for four or five days with febrile disturbance and exacerbation of his rheumatic pains. Cultural examination of all the teeth gave a free growth of streptococci of two strains—(1) a hæmolytic streptococcus; (2) a non-hæmolytic streptococcus. Since removal of these foci patient is steadily improving and I believe the prognosis is favourable.

In all these eight cases the radiographic findings were confirmed, and every tooth (all teeth were removed with meticulous care to avoid contamination from the mouth) submitted to bacteriological examination gave a growth of pyogenic organisms. As far as the series of 70 cases is concerned, this report must of necessity be looked upon as a preliminary communication, owing to the recent nature of the work detailed. My experience is so small that it would be unwise for me to dogmatise, and to say, for example, that apical infection was the "fons et origo mali" in every case in which it was discovered. At the same time that experience has been large enough to convince me that apical infection is frequently the cause of constitutional disease, which may be prevented or cured, particularly if recognised at an early stage.

It seems that a new conception of oral sepsis must revolutionise dental practice. Our dental surgeons have attained a high degree of skill in preserving the visible portion of the teeth; they have concentrated their energies almost entirely towards their preservation for masticatory and cosmetic purposes. A well-known American writer gives it as his considered opinion that the degree of oral sepsis is in direct proportion to the amount of mechanical work in the mouth. One has often admired the mechanical skill of the dental surgeon revealed in beautiful bridge work, crowns, fillings, &c.; yet the whole has sometimes to be scrapped in order to give their host health. For some time past I have questioned whether a devitalised tooth should ever be left in the head, and am now sure that it should not unless apical infection has been excluded by radiographic examination repeated at stated intervals. The dental surgeon will in the future visualise his work primarily from the standpoint of oral sepsis. He will consider the mouth as a gateway of disease, and himself as the keeper of the gate.

Thanks are due to my colleagues, Dr. Sinclair Miller, D.S.O., for the pathological examinations, and to Dr. C. W. S. Saberton and Dr. C. G. Hitchcock for radiographic help.

EXPERIMENTS WITH THE FLOCCULATION TEST (SACHS-GEORGI) FOR SYPHILIS.

BY W. R. LOGAN, M.D. EDIN., F.R.C.P. EDIN.,
CLINICAL PATHOLOGIST, ROYAL INFIRMARY, EDINBURGH.

SOON after Wassermann introduced his reaction it was shown by numerous workers that the extract of spirochætes (syphilitic liver) which was used as antigen could be replaced by certain lipoid substances,[1] and that the reaction was not therefore necessarily a genuine antigen-antibody reaction. Further work afforded evidence that the reaction was of a physical kind,[2] and that the reacting power of the serum seemed to lie in the globulin fraction;[3] in addition it was shown that syphilitic sera possessed, to a greater degree than normal sera, the power of producing precipitates when left in contact with certain lipoidal emulsions under certain conditions.[4] It has for many years been a well-established fact that there is an optimum turbidity of the antigen for the production of the Wassermann reaction,[2] that is, a physical state when there is an optimum total surface of the suspended lipoids,[5] a fact which is taken as strong evidence of the physical nature of the reaction. The prevailing view of the Wassermann reaction may be summarised as follows: that the reaction is of a physico-chemical nature, and that there occurs a precipitation of the globulin of the syphilitic serum by the lipoidal colloids of the antigen with adsorption of the complement by this precipitate.[5] [6] It is suggested that fixation of complement does not occur in the absence of such precipitation or flocculation, even though at the time the reaction takes place flocculation is not demonstrable to the naked eye, but convincing experimental proof on the point is still lacking.

Attempts to Replace the Wassermann Test

On this assumption attempts have been made to replace the very complex Wassermann reaction by one in which a visible flocculation could serve as evidence of the syphilitic nature of the serum and render unnecessary the measurement of the amount of complement fixed by the protein-lipoid mixture. Of these various attempts the most successful up to the present time appears to be that advocated by Sachs and Georgi,[8] and the method is known in Germany under the name of the Sachs-Georgi test.

Sachs and Georgi[8] made use of the mixture of heart extract and cholesterin,[7] which is widely used in this country as the antigen in the Wassermann reaction, and mixing this with the diluted serum in certain proportions they noted the production or not of a flocculus after incubating the tube for two hours at 37° C., and then leaving at room temperature overnight. They claimed for this method great reliability in the distinction of syphilitic from non-syphilitic sera, a greater reliability, indeed, than they allowed to the Wassermann test itself. A large number of other workers have recently applied the method with conflicting results; some agreed as to the reliability of the reaction, while others found that the methods failed to give positive reactions in many cases which were syphilitic, and that false positives were given in other conditions, as, for example, in tuberculosis. Sachs and Georgi,[9] in a second paper, admitted that they had claimed too high a degree of accuracy for the test, but stated that with an increase in the length of incubation the false positives could be eliminated. They now suggested that the test should not be used to supplant the Wassermann test, but rather to supplement it. Other workers have also found this modification of the reaction to give more reliable results, and since its introduction the bulk of opinion in Germany has been in favour of the accuracy of the test. It is evident, however, that the experience of a very large number of workers must be collected before a reliable estimate of its accuracy can be made, and the time has not yet arrived for the collection of this evidence; the amount of work on this reaction which has been carried on outside Germany is up to the present very small.

The main results are here shown. "B." signifies an extract prepared from bullock's heart, while "H." is that prepared from human heart. "R.T." signifies room temperature.

Technique.

The lipoidal mixture used by Sachs and Georgi is prepared as follows:—

An alcoholic extract of bullock's heart is made, using 1 g. of heart muscle to each 5 c.cm. of 96 per cent. alcohol; 100 c.cm. of this heart extract is mixed with 200 c.cm. of 96 per cent. alcohol and 13 c.cm. of 1 per cent. cholesterin (alcoholic solution). This cholesterinised extract is diluted with normal saline, just before the test, in the following way. To 1 volume of the mixture 1 volume of normal saline is rapidly added, and then 4 volumes of saline added more slowly in such a way as to make an emulsion which is opalescent but not turbid. The serum of the patient inactivated at about 55° C., as for the Wassermann test, is diluted 1 in 10 with normal saline, and to 1 c.cm. of diluted serum is added 0·5 c.cm. of emulsion prepared in the manner described. In their original paper Sachs and Georgi recommended that the results should be read off at the end of two hours at 37° C., and 18–20 hours at room temperature, but in their later paper they recommend as yielding more reliable results leaving the tubes in the incubator for 18–20 hours and reading off immediately on removal therefrom. A positive reaction is one in which there is a flocculation or precipitation visible to the naked eye or with the aid of a hand-lens.

In the series of experiments here reported the following technique was used:—

The bullock's heart extract was prepared according to the above formula, the minced meat being shaken up with the alcohol but not ground in a mortar. The human heart extract was, however, prepared in a slightly different manner so as to use the extract from which the "antigen" used in the parallel Wassermann tests was prepared—that is, a 1 in 10 alcoholic extract of human heart muscle was used, the muscle being ground in a mortar with the alcohol; on the day of the test 20 parts of the extract were mixed with 10 parts of absolute alcohol and with 1·35 parts of 1 per cent. cholesterin (Poulenc frères). One part of this mixture was then diluted with 5 parts of saline so as to give varying degrees of density. It was never possible to produce an opalescent solution with this extract, the thinnest obtainable being slightly turbid.

Wassermann tests were conducted on all the sera by a method which is practically that of Harrison,[10] differing only in that the doses of complement used in the test are 4, 6, and 8, or 4 and 8, and that the volume of each constituent used is 0·2 c.cm.

A +++ (strong positive) represents eight doses or more of complement fixed, ++ (moderately strong positive) between six and eight doses, + (weak positive) between four and six, and ± (doubtful reaction) less than four but more than the negative controls. In every series of tests at least two negative controls and at least two strong positives in addition to other positives of different degrees were invariably used. Every precaution was taken to eliminate complement that was over-deviable and antigen that was too anticomplementary and which might have given false positives. In addition, every case included in this series had both its Wassermann and its Sachs-Georgi done by one worker (myself) from the same tube of serum (heated at 56° C. for 20 minutes), and with the exception of one series both tests were done on the same day. In every case venous blood has been used. The +++ may be taken with certainty to represent cases of syphilis, while the ++ and + were with extremely few exceptions obtained from early cases and cases under treatment. The ± reactions are not necessarily, though frequently, from latent or treated cases.

It was early apparent that opalescent emulsions such as Sachs-Georgi recommend give results in the interpretation of which there is room for important differences of opinion. The flocculation is so very delicate that many cases occur in which one is doubtful whether the reaction should be classed as positive or negative. Attempts were therefore made to modify the test in such a way that the flocculation in a strong positive case should be massive and unmistakable and at the same time to ensure that the negative cases should show no trace of flocculation. The conditions have, therefore, been varied so as to test different time and temperature readings, different cholesterinised extracts, and cholesterinised extracts prepared so as to be under different conditions of density.

Some sort of scale had to be drawn up to accommodate the readings to the use of the dense lipoidal extracts used in the later experiments, and the following standards were adopted for convenience in recording:—

+++ was used to represent complete clearing of the emulsion with the formation of large flocculi which usually come to the surface or adhere to the side of the tube; ++ represents a result in which there is clearing but in which the flocculi are more numerous but not so massive; + represents an appearance in which there is not complete clearing between smaller flocculi; ± represents the production of very small flocculi which are still visible to the naked eye; ∓ a flocculation which is only with certainty distinguishable with the help of a hand-lens; and –, no visible change in the emulsion even with the help of a hand-lens. In the interpretation ± to +++ are reckoned as positive, that is those degrees of flocculation which can with certainty be determined by the naked eye; ∓ is classed as a doubtful reaction; and – as negative.

The number of different sera used was 686, and the number of different tests and readings 1882.

Discussion of Results.

In discussing the results obtained one may for convenience first take Series I. to V.

Emulsions.—Both the opalescent emulsion produced from the bullock's heart extract and the slightly or moderately turbid emulsion produced from the human heart extract showed fluctuations at different testings in the degree to which they yielded results comparable with those of the Wassermann tests; when tested side by side, as in Series II. and III., the opalescent emulsion gave results rather nearer to the Wassermann readings in Series II., but much less close in Series III. In addition, what it has not been possible to demonstrate in the table, the slightly or moderately turbid emulsion gave much more definite and more easily read results than did the opalescent emulsion. Although both emulsions on occasion yielded results very closely analogous to the Wassermann readings, both gave on other occasions results which materially differed, usually in the direction of missing undoubtedly syphilitic cases.

Time and temperature.—Here also the results were not perfectly consistent. The original Sachs-Georgi standard method of 2 hours at 37° C. followed by 20 hours at room temperature gave results in which a few positives were negative, and a few negatives positive; a reading at the end of 14 hours at 37° C. similarly showed results on the negative side; readings at the end of 24 hours at 37° C. gave, as a rule, results in which a few positives were missed, while readings at the end of 48 hours gave, as a rule, results tallying fairly closely with those of the Wassermann. At this later period, however, there was a tendency for negative Wassermann sera to give a weak positive Sachs-Georgi result.

In Series VII. to XI. turbid emulsions were used, the last series being one in which a set of emulsions of varying turbidity, prepared from the same extract, were tested side by side with the same set of sera. The results of these later experiments may be summarised as follows:—

Emulsion.—Where in the same series of tests emulsions of varying density were used (Series XI.) it was found that turbid emulsions gave better results than opalescent, but that greater degrees of turbidity beyond a certain minimum did not seem to produce a difference in the readings.

Time and temperature.—Readings at the end of 42 or 43 hours at 37° C. as a rule gave the most accurate results; readings at the end of 20 to 24 hours gave results usually slightly on the negative side; readings at the end of 15½ hours at room temperature gave results in which all the positives would be regarded as negative; readings at the end of so many hours at room temperature, followed by so many hours at 37° C., gave results less good than readings at the end of so many hours at 37° C. followed by so many hours at room temperature.

False positives.—One may now turn to Series IX., where false positives were yielded by all the negative sera. The reason for such a result is not yet definitely known, but it is significant that on this occasion, owing to the large number of tests which were being carried out, a batch of new tubes, which had been somewhat hurriedly washed, was pressed into service. As other factors in the reaction were the same as on other occasions, it is possible that the electrolytic conditions which play their part in the reaction had been on this occasion artificially produced. It will be seen that false positives were also given at the 43 hours' reading of Series X.

One may therefore add to the conclusions already made: under conditions as outlined, results can usually be obtained by the flocculation test, which approximate extremely closely to those of careful Wassermann tests, and in my hands the most accurate and most easily read were obtained when turbid emulsions were used rather than the opalescent solutions advocated by Sachs and Georgi, and when a considerably longer period of incubation was made use of than their standard time of 18 to 20 hours. It must be admitted, on the other hand, that the series of false positives already referred to occurred when these thick emulsions were being used, and it is possible that the increase in the surface of the suspended lipoids carries with its advantages this particular danger. I believe, however, that on this occasion the cleaning of the glassware had been insufficient. When opalescent solutions are used, the readings seem to me to be too difficult and too liable to cause the introduction of a personal element, and for this reason it is desirable that the comparatively gross flocculation seen with the thicker emulsions should be aimed at in standardising the test. Until the factors which may cause false reactions are definitely recognised and can be controlled the test should not be used to supplant the Wassermann reaction, although it may profitably be used as an additional control to that test. Even when used in this way at least half a dozen negative and half a dozen positive controls should always be included. Further experiments into the nature of the reaction are in progress.

A CASE OF

ENTERIC FEVER DUE TO THE B. ENTERITIDIS OF GAERTNER.

BY A. B. ROSHER, M.R.C.S., L.R.C.P. LOND., D.P.H.,
ASSISTANT CLINICAL PATHOLOGIST, CHARING CROSS HOSPITAL;
AND
G. SELBY WILSON, M.D., M.R.C.P. LOND., D.P.H.,
DEMONSTRATOR IN BACTERIOLOGY, INSTITUTE OF PATHOLOGY, CHARING CROSS HOSPITAL MEDICAL SCHOOL.

THE following is a report of a case running a course simulating in many respects that of a case of typhoid fever, but due in all probability to infection with the *Bacillus enteritidis* of Gaertner. We feel constrained to publish it, not merely because it presents features of inherent bacteriological interest, but because it appears to be a unique case of its kind. Not that infection with the *B. enteritidis* of Gaertner is uncommon, but infection with this organism, occurring in a sporadic form, unassociated with other cases, having no demonstrable relation to food-poisoning, and running a course so closely similar to that of typhoid fever, appears to be unrecorded. Savage,[1] for instance, has collected the details of no less than 19 outbreaks of food-poisoning, shown more or less conclusively to have been due to the *B. enteritidis* of Gaertner, but amongst these there does not appear to be a single instance of a case running a typical typhoid course, such as the one we are about to describe. Bainbridge,[2] it is true, in his Milroy lectures in 1912 stated that "the illness following the consumption of meat infected with Gaertner's bacillus or *B. suipestifer* may take the form of pyrexia, lasting two to three weeks," but he quotes no instances in support of this statement, nor does he mention whether such cases are sporadic or merely associated with outbreaks of food-poisoning. It is the two points, the typhoid-like course and the sporadic nature of the infection, upon which we desire to lay special emphasis. Undoubtedly there have been some rather anomalous cases of infection with the *B. enteritidis*, and perhaps it would be advisable to give a short résumé of such as we have been able to collect from the literature.

Anomalous Cases of Infection.

Dean,[3] in 1911, reported a case of cholecystitis with gall-stones in a woman, aged 61, in which the *B. enteritidis* of Gaertner was isolated from the fluid in the gall-bladder, from a gall-stone, and from the fæces. The bacteriological findings were confirmed by serological and absorption tests. There was apparently no history of enteric fever or other illness which might be ascribed to the passage of the organism into the gall-bladder, so that in all probability it had gained entrance to the body without giving rise to marked symptoms.

Buchanan,[4] in a report to the Local Government Board, described an outbreak of food-poisoning at Mansfield following on the consumption of potted meat. Amongst the sufferers was a boy who had a prolonged illness without diarrhœa, was restless and feverish, delirious in the second week at night, wasted rapidly, ran a temperature of 101°-103° F., with a pulse of 120 and respirations of 30 a minute, had abdominal pain, some cough, frontal headache, slight enlargement of the spleen, and improved gradually after the fourth week. No definite bacteria were isolated and no agglutination tests of the boy's serum were performed. Possibly this may have been a case of infection with *B. enteritidis*, but, as apart from the finding of *B. proteus* in the potted meat no organisms of pathogenic importance were encountered, the exact nature of the case must remain in doubt.

Savage,[5] in an investigation of human fæces, isolated the *B. enteritidis* of Gaertner from the stools of a patient—age and sex not stated—who was clinically suffering from typhoid fever. The patient was admitted to hospital on the 28th day of illness; 12 days later—i.e., on the 40th day—a perforation of the intestine occurred; he was operated upon and died. On the 30th day the patient's serum agglutinated *B. typhosus* in a dilution of 1-200, and two strains of paratyphoid bacilli in a dilution of 1-100. On the 36th day the titre to *B. typhosus* was 1-600, to the paratyphoid bacilli 1-100. On the 38th day the stools were examined, and two organisms of the Gaertner group isolated; of these one was agglutinated by the patient's serum in a dilution of 1-100. This organism gave the biological reactions of the *B. enteritidis* of Gaertner, and was agglutinated to titre by a Gaertner serum. It is possible that this was a case of enteric fever due to the *B. typhosus*, and that by the time that the fæces were examined—that is, on the 38th day of illness—the organism had disappeared from the stools. The *B. enteritidis* isolated may have been introduced casually into the patient's intestine, or it is possible that it normally formed part of the intestinal flora, though both of these conditions appear to be extremely uncommon, as Savage himself has shown. If it is admitted, however, that the *B. enteritidis* was actually the cause of the illness, it is difficult to account for the agglutination results of the patient's serum; this serum rose in titre from the 30th to the 36th day from 1-200 to *B. typhosus* to 1-600, while the titre for the paratyphoid bacilli remained constant at 1-100. Unfortunately no absorption reaction was performed to see if the *B. enteriditis* isolated from the fæces would absorb the agglutinins for *B. typhosus* from the patient's serum. Further, as the patient's serum was not repeatedly tested against the *B. enteritidis*—indeed, from the account it seems doubtful if this was done at all—it does not appear justifiable to pronounce any definite opinion as to the exact nature of the infection.

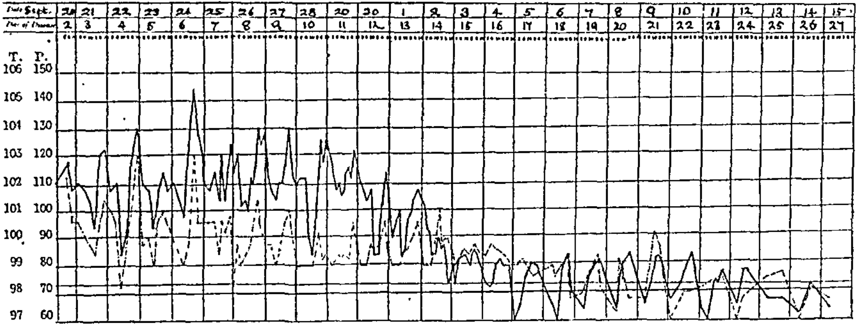
Savage,[6] in his recent book on "Food Poisoning and Food Infections," says that Batten and Forbes in 1908 described two cases of infection of infants with the *B. enteritidis* of Gaertner. The two patients suffered from diarrhœa and vomiting, with a considerable amount of pyrexia, the symptoms persisting for a number of weeks and ending fatally in both cases. No evidence was available as to the manner of infection. In the same book Savage,[7] when dealing with the symptomatology of food-poisoning, remarks that very occasionally cases with a protracted course are met with, the patients being ill for several weeks. However, these cases are met with in outbreaks of food-poisoning due to several different types of organism, and are obviously different from sporadic cases of infection with the *B. enteritidis*.

Description of Case.

The patient, Miss X, aged 23, who was temporarily acting as resident house physician, on awaking on Sunday morning, Sept. 19th, 1920, found herself to be suffering from a general feeling of malaise, together with a dry irritating cough. She got up and went about her duties. During the course of the day the cough continued incessantly, without, however, any expectoration of sputum. In the afternoon she went out to tea, and on returning in the evening felt hot and feverish. On taking her temperature she found it to be 100·4° F. After supper she took 30 grains of aspirin and then danced for an hour. Before going to bed at 10 P.M. her temperature had dropped to 99°. Sleep during the night was disturbed very badly by the cough. The following morning she was feeling distinctly worse, and as her temperature had risen to 102° she was admitted to one of the wards of the hospital. On admission the temperature was 102·8°, pulse 112, and respirations 28. The cough appeared to be somewhat looser, and a certain amount of mucoid expectoration was brought up.

Physical examination.—We are indebted to Dr. W. J. Fenton for the account of this examination, which was completely negative, except for the presence of an occasional rhonchus at the bases of the lungs. It was thought that the condition was probably one of influenza, of which there had been two or three cases amongst the nursing staff at that time.

CHART 1.



Showing the temperature (T.) curve as a continuous line and the pulse (P.) curve as an intermittent line.

During the next few days the temperature rose gradually, with marked morning remissions of 2° or 3° F., till by the 6th day of disease it had reached 103·4°; the pulse, on the other hand, gradually decreased in frequency till on the same day it was only 86; the respirations similarly decreased to 22 per minute. The cough had become looser and the expectoration, which was now more profuse, was mucopurulent in nature and sometimes tinged with blood; examination of the sputum for tubercle bacilli was negative. On auscultation of the lungs at this stage râles were heard at both bases, while scattered over the left base a large number of moist sounds were audible, which were taken to be evidence of patches of broncho-pneumonia. No dullness on percussion was demonstrable. During the first week the patient's appetite was fairly good, and she was able to take a semi-liquid diet without experiencing any discomfort. An expectorant mixture was given three times a day, together with inhalatio tereben. co.

The condition of the patient then became somewhat graver. The temperature oscillated between 101° F. in the morning and 104° in the evening, the pulse varied between 80 and 100, while the respirations rose to about 46. The facies of the patient, which had at first been bright and intelligent, assumed a dull, heavy, listless, apathetic appearance; the tongue was dry and heavily coated with fur; the lips were cracked and covered with sordes; at night there was low muttering delirium with purposeless movements of the fingers. No abdominal pain was complained of, the bowels were constipated and had to be relieved by enemata, and no enlargement of the spleen could be made out.

First agglutination test.—On Sept. 30th, the 12th day of illness, it was thought advisable to test the patient's serum for agglutinins to the enteric group. Accordingly, it was put up against *B. typhosus*, *B. paratyphosus A*, *B. paratyphosus B*, two strains of *B. paratyphosus C*, eight strains of *B. suipestifer*, and *B. enteritidis* of Gaertner. It failed to agglutinate any of them in a dilution greater than 1-20, with the exception of *B. enteritidis*, which was agglutinated up to 1-160. The technique used for this and for subsequent agglutination experiments was a Dreyer's technique, modified only in that standardised agglutinable cultures were not employed, the tubes being incubated in a water-bath for two hours at 55° C, and read a quarter of an hour later.

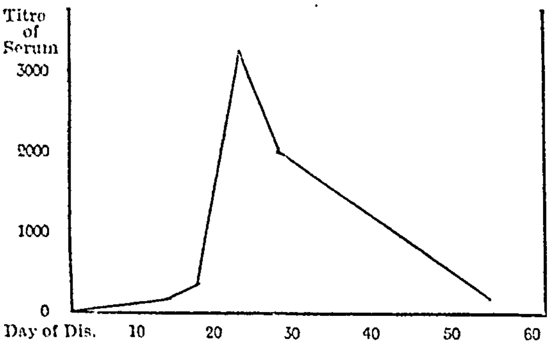
First Leucocyte count.—On the same day a differential white blood cell count gave the following figures:—

Total white blood corpuscles	11,062 per c.mm.
Polymorphonuclear leucocytes ...	88 per cent.
Small lymphocytes	9 ,,
Large lymphocytes	1 ,,
Eosinophiles	1 ,,
Basophiles	Nil.
Large hyalines	1 per cent.

On the same day a blood culture was also performed, but proved negative. On the 12th day the temperature began to fall, dropping to 99·4° while the pulse remained at 86, and the respirations decreased to 36 per minute. Simultaneously the appearance of the patient became brighter, the face lost its dull expression, and the tongue began to clear.

Second agglutination test.—On the 16th day of disease, when the patient was sitting propped up in bed, but still feeling very weak, the serum was tested again, and it was found that the titre to *B. enteritidis* had risen to 1-320. On the 14th day examination of the fæces and the urine for organisms of the enteric group was undertaken, the result being negative. The fæces were examined on five occasions during the rest of the time the patient was in hospital, but apart from the presence of *B. pyocyaneus* no non-lactose fermenters were isolated. The reason for not examining them every day was firstly, because the patient did not pass a motion every day; and secondly, because there was some misunderstanding over the collection of the specimens, leading to the failure of their transmission to the laboratory.

CHART 2.



Showing the agglutination curve of the patient.

By the 14th day the temperature had dropped to normal, but remained swinging between 97° and 99° for the next ten days, when it finally became stable on the 25th day after the commencement of the illness. The pulse ranged between 68 and 84, while the respirations dropped to 20-24 per minute. Convalescence was extremely rapid, the patient by the end of the third week being able to sit up in bed, carry on an animated conversation, and take light solid articles of food.

Third agglutination test.—On Oct. 10th, the 22nd day of illness, the titre of the serum for *B. enteritidis* had risen to 1-3200.

Second leucocyte count.—Three days later a second count was performed, and showed:—

Total white blood corpuscles	8100 per c.cm.
Polymorphonuclear leucocytes	72 per cent.
Small lymphocytes	22 ,,
Large lymphocytes	1 ,,
Eosinophiles	3 ,,
Basophiles	1 ,,
Large hyalines	1 ,,

Fourth agglutination test.—On the 27th day of disease the titre of the patient's serum to *B. enteritidis* had fallen to 1-2000.

The patient got up on the 25th day for a short time, and was feeling so well that she was allowed to leave hospital on Oct. 15th, 27 days from the commencement of the attack. She was away for three weeks on the south coast. During that time she felt very weak, and suffered from occasional attacks of vomiting, coming on in the evening after exercise. There was no diarrhœa and the appetite was good. The patient bled herself on Nov. 2nd, but unfortunately the blood was delayed in transit, so that by the time it reached the laboratory it was in a state unfit for examination.

Fifth agglutination test.—On her return she was bled again, and her serum now agglutinated *B. enteritidis* only in a dilution of 1-160. Chart 2 shows the agglutination curve.

Diagnosis.

Making a résumé of the chief features of the case we have, then, (1) a fever lasting altogether 24 days and running a course simulating closely that of typhoid; (2) a very definite lowering of the pulse-temperature ratio, particularly noticeable when the pyrexia was at its height; (3) a moderate degree of toxæmia during the second week; (4) absence of a rash; and (5) no evidence of enlargement of the spleen. We do not consider the absence of the rash to be of great importance, as its presence is by no means constant, especially in cases of paratyphoid infection, while in connexion with the spleen, as a physical examination of the patient appears only to have been made infrequently, owing to her weak condition and the desire to disturb her as little as possible, and as it is recognised that the spleen may only be palpable for one or two days during the whole course of typhoid fever, we feel that it is impossible to exclude enlargement of this organ. Further, we can find no evidence to show that either a rash or enlargement of the spleen are at all common accompaniments of infection with the *B. enteritidis* of Gaertner. Certainly, in reviewing the literature of food-poisoning, one cannot help but be struck by the rarity with which these two symptoms are encountered.

A blood culture taken on the 12th day of disease was negative, and this, again, is a point on which too much stress cannot be laid, as by this time agglutinins had appeared in the blood, and as it seems possible that these may lead to the clumping of the bacilli in vivo and their subsequent removal from the blood by filtration in such organs as the liver, spleen, and kidneys, a positive result is hardly to be expected at this stage of the disease; in support of this we think we are justified in saying that the majority of pathologists will agree that the chances of obtaining a positive culture from the blood diminish every day after the end of the first week of illness.

The examination of the fæces and urine was likewise not undertaken till comparatively late in the disease—in fact, till the very day on which the temperature began to fall—so that here again negative findings are not of any great value. On the other hand, the characteristic agglutination curve, rising rapidly during the third week, falling sharply with the complete establishment of convalescence, and then coming down more slowly and remaining well above normal for at least seven weeks is a point which we consider to be of the greatest importance in the diagnosis of the disease. We realise, however, the incompleteness of the evidence necessary for the complete establishment of the nature of the case, and only regret that, as laboratory examination was not undertaken till the 12th day of illness, more extensive investigations were unable to be carried out.

Suggested Interpretations of the Case.

The following hypotheses suggest themselves as interpretations of the findings of the case:—

(1) The agglutination curve, though perfectly distinct, may have been in the nature of a pure freak—that is to say, that agglutinins to the *B. enteritidis* of Gaertner may be present in the serum of an individual (normal or diseased) who is not suffering from an infection with this organism. In this connexion we have been unable to find in the literature any account of an examination made with the object of estimating the normal agglutinin titre of human sera to *B. enteritidis*, such as has been carried out so fully in the case of *B. typhosus* and *B. dysenteriæ*, Flexner, and it is therefore impossible to exclude the fact that in certain individuals, under certain circumstances other than infection with the Gaertner bacillus, agglutinins for this organism may be present. But considering the number of agglutination tests which must have been performed against *B. enteritidis* in relation to the food-poisoning outbreaks, it would seem improbable that, if this hypothesis were true, it would not have been verified previously. It may be objected that the emulsion used for agglutination in this particular case was at fault. With the exception of the last test on the 53rd day after the commencement of the illness the same emulsion was employed throughout. The organism used was *B. enteritidis* of Gaertner, obtained from the Lister Institute, being

one of the strains with which Bainbridge worked in 1911 during his classification of the Gaertner group; it was grown in broth for 24 hours at 37° C., was then heated at 55° C. for one hour, and formalin added subsequently to the extent of 1 per cent. This emulsion was being used at the time very extensively by one of us (G. S. W.) while working out the relation of some organisms of the paratyphoid group, and though it was tested against a large number of sera, both rabbit and human, no instance of non-specific agglutination was encountered. Moreover, neither during the past 18 months, in which an extensive series of agglutination tests have been used with this strain, nor during the past few weeks in which it has been employed almost daily, have any anomalous cross-agglutinations been met with. Finally, both the saline and the normal rabbit serum controls, which were put up with each test, have proved consistently negative.

(2) The clumping of *B. enteritidis* may possibly have been due to heterologous agglutination, secondary to infection of the patient with an organism having an antigenic constitution similar to that of the Gaertner bacillus. As, however, no less than 18 other strains of the paratyphoid-Gaertner-suipestifer group were tested against the serum with negative results it is improbable that the infecting organism could have belonged to this group. In that case it must have been some entirely different bacterium, the serological reactions to which have not been worked out. However fantastic this may seem, we would recall the case of the Weil-Felix reaction in typhus fever, in which an apparently non-pathogenic proteus bacillus is agglutinated by the serum of a patient infected with an organism of undetermined nature. It would be unwise, however, to press this analogy too closely, as we remain completely in the dark as to its exact nature.

(3) The patient may have been previously infected with the *B. enteritidis*, and agglutinins against this organism formed in her blood. The occurrence of a pyrexial wave may then have stimulated the fresh production of these agglutinins, with the result that a distinct agglutination curve was produced. Garrow,[8] in a recent paper, has invoked this hypothesis, based upon a certain amount of experimental evidence, to explain the rise in agglutinin titre to organisms of the typhoid and paratyphoid groups which has been found to occur in undoubted cases of malaria and trench fever, the patients having previously received one or more injections of T.A.B. vaccine. Against this there are four salient facts: (*a*) there is no evidence of previous infection with the Gaertner bacillus, and a critical examination of the patient's past history failed to reveal any facts in favour of this possibility; (*b*) the patient had never had an injection of T.A.B. or other vaccine, so that group agglutination resulting from such an injection can definitely be rejected even if one were prepared to admit that the injection of such a vaccine could lead to the formation of agglutinins acting on the *B. enteritidis*; (*c*) the course of the disease was highly suggestive of enteric fever, and since, therefore, the clinical and bacteriological findings agreed closely with each other, the objection that the diagnosis was made on laboratory investigation alone cannot be maintained; and (*d*) there is no definite evidence in human beings to prove that a pyrexia of non-enteric nature is able to give rise in a patient who has previously suffered from an enteric infection or who has received a prophylactic dose of T.A.B. vaccine to an agglutination curve similar to that which results as a reaction to infection with an organism of the enteric group.

(4) The case was one of infection with the *B. enteritidis* of Gaertner, in favour of which is the definite agglutination curve, which has been found to be so characteristic of infections with organisms of the enteric group. We feel that in favour of this hypothesis is the vast amount of work which has been performed on this subject by Dreyer and the Oxford School—work which has both been confirmed and amplified by Topley, Platts, and Imrie[9] while investigating cases of undiagnosed pyrexia invalided from the Western front during the late war.

Method of Infection.

Accepting the diagnosis of Gaertner infection as correct, the question naturally arises as to how the patient became infected. At the time there was no case of enteric fever in the hospital, with the exception of one man who was suffering from a prolonged illness, shown to be due to infection with an organism of the Aertrycke mutton type. As the serum of this patient, however, showed no agglutinins to the *B. enteritidis*, it is quite improbable that there was any connexion between the two cases. Miss X had the majority of her meals in the residents' quarters, but a few had been taken outside. When she was first interrogated at the end of the second week of her illness she was unable to give any clear account of the food she had partaken of during the few days preceding the commencement of her symptoms, and therefore an examination of such food was out of the question. Nor could she remember having eaten any article of diet which had appeared to her to be in any way suspicious. A friend of hers—also resident in the hospital—who stated that she had had all her meals during the previous week with Miss X, admitted to having experienced a certain degree of malaise on the Sunday morning on which Miss X first felt ill, which continued for a few days before passing off, but as no definite symptoms were noticed, it would be unwise to regard this as more than a coincidence. None of the other resident staff nor any of the patients or nurses in hospital at the time manifested any evidence of food-poisoning, so that it would appear that the infection probably occurred outside the hospital.

If, however, infection had occurred through consumption of food in the hospital, four possible sources suggest themselves: (1) The food, when introduced into the hospital, may have been infected. Several examples of milk and meat containing the *B. enteritidis* of Gaertner have been reported; Zwick,[10] for instance, isolated a Gaertner bacillus from the milk of two cows suffering from acute mastitis, while Mohler and Buckley[11] recovered Gaertner bacilli from the fæces of a number of cows suffering from an enzoötic of enteritis, while Savage's extensive work on the subject has shown that infection of cows with the *B. enteritidis* is not altogether uncommon. However, this possibility is negatived by the fact that no symptoms of food-poisoning occurred in the other inmates of the hospital, as would almost certainly have happened if this had been true. (2) The cook, who prepared the food for residents, nurses, and patients, may have been a carrier of *B. enteritidis*, and thus have infected the food. If this were so, one would have expected other examples of food-poisoning to have occurred, which, as already mentioned, was not the case. Examination of this cook and her co-workers in the kitchen for evidence of infection was found to be impracticable, and as it seemed to be a most unlikely source, no further attention was devoted to this possibility. (3) The housemaid who carved the meat and served the food to the residents may have been a carrier, and may have infected one or two portions of food while engaged in its distribution; this might account for only one person being affected with symptoms of food-poisoning. To test this hypothesis the serum of the housemaid was taken and put up against the *B. enteritidis* of Gaertner and against one of the suipestifer group, but was found to be completely negative. (4) The food consumed by the patient may have received a chance infection from a fly, which had been in contact with Gaertner-containing material. By this means it is possible that only a small amount of food might have been contaminated—probably after it had been cooked—with the result that risk of infection would have been incurred by only one or two individuals, and as the infectivity of the *B. enteritidis* does not appear to be of a very high degree, unless it has multiplied in the food so as to be present in relatively large numbers or exists combined with a considerable amount of preformed toxin, it is quite reasonable to suppose that only such persons as presented a general lowering of resistance would be likely to succumb to the effects of invasion by the organism. In the very nature of the case it was impossible to prove the truth of such a hypothesis.

Previous Medical History of the Patient.

Having failed to find any definite evidence of infection, the past history of the patient was closely investigated, and the following facts elucidated. Two years ago she had suffered from a severe attack of influenza when at Sheffield, at the time when this disease was manifesting a pandemic spread, during which she had run a high temperature for two to three weeks, accompanied by severe vomiting and hæmorrhages from the nose and mouth. Altogether she was in bed for five weeks, and had felt somewhat weak for a year afterwards. Last Christmas, when away in the country staying with her sister, who had returned from India after a prolonged attack of sprue, she had had another attack of fever, likewise diagnosed as influenza, starting with a high temperature and vomiting, which persisted for three or four days. A week after her recovery she was attacked with abdominal pain followed by diarrhœa with the passage of blood and mucus, which continued for nearly ten days before finally passing off; during this time the patient continued up and about, though feeling very weak. Since then she has had a slight degree of debility, and has been unable to take any violent exercise. It was thought possible that the patient might have been infected with an organism of the dysentery group from her sister, though the latter apparently never had anything to do with the preparation of the food in the house. To test this the serum of the patient was put up on Oct. 4th, the 16th day of her illness, against emulsions of *B. dysenteriæ*, Flexner, *V*, *W*, *X*, *Y*, *Z*, and against one of *B. dysenteriæ*, Shiga, but the agglutinations were all negative in a dilution of 1–50.

There yet remains the possibility that her sister may have been infected with the *B. enteritidis*, and from her Miss X had become infected with the resulting illness marked by abdominal pain and diarrhœa. Failing to rid herself entirely of the organism she had remained a carrier, and her recent illness might have been due to an exacerbation of the activity of this organism occurring while the patient was in a debilitated condition. Unfortunately, as her sister does not live in London it has not been possible as yet to procure a sample of her blood for examination, but if occasion offers this will certainly be done.

Summary.

(1) A case is reported of a patient suffering from pyrexia which simulated closely a typhoid course, but which was probably due to infection with the *B. enteritidis* of Gaertner. The case, moreover, was of a purely sporadic nature, and was unconnected with any coexisting outbreak of food-poisoning.

(2) It is suggested that it would be advisable in view of this case to test the sera of patients suffering from enteric-like infections against a more extended series of antigens than are commonly employed, in order to ascertain whether sporadic infections with organisms of the enteric group other than *B. typhosus*, *B. paratyphosus A*, and *B. paratyphosus B* are more than mere pathological entities.

It is with pleasure that we record our gratitude first of all to Dr. Fenton for his kind permission in allowing us to publish the case; secondly to Dr. W. W. C. Topley, director of the Institute of Pathology, Charing Cross Hospital Medical School, for giving us advice from his extensive bacteriological experience of cases of enteric infections; and, thirdly, to the clinical staff of the hospital for the help and facilities they afforded us.

PSEUDO-COXALGIA:

OSTEO-CHONDRITIS DEFORMANS JUVENILIS.

BY H. A. T. FAIRBANK, D.S.O., O.B.E., M.S. LOND., F.R.C.S. ENG.,

SENIOR ORTHOPÆDIC SURGEON TO KING'S COLLEGE HOSPITAL; SURGEON TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON.

So little attention has been paid to the above affection in this country, except by orthopædic surgeons, that a brief description of what is known of the disease may be of interest, and may result in greater numbers of these cases being recognised and recorded. Since the appearance some ten years ago of the original papers dealing with the subject, by A. T. Legg in America, J. Calvé in France, and Perthes in Germany, little has been written on the subject in this country. Cases have been reported by R. C. Elmslie, D. P. D. Wilkie, H. H. Platt, E. M. Little, and the writer, while Mr. Muirhead Little published a short paper on this subject in the *Clinical Journal* in 1915. An exhaustive paper by Legg on the facts and theories to date may be found in *Surgery, Gynæcology, and Obstetrics* of the following year. The chief importance in recognising this condition lies in the difference between its prognosis and that of tuberculous hip disease, for which it is not uncommonly mistaken. Juvenile osteo-chondritis, which is by no means rare, affects children from 3½ to about 12 years of age, and males more commonly than females; it is usually unilateral, but may be bilateral.

Description of a Typical Case.

A healthy-looking child of, say, 6 years of age, of an active disposition and fond of games, begins to limp on one leg; perhaps there is a history of some antecedent fall on the hip, but not such as would raise a suspicion of any serious injury; the limp persists, and is accompanied by little or no pain. Eventually advice is sought, and examination reveals the following facts.

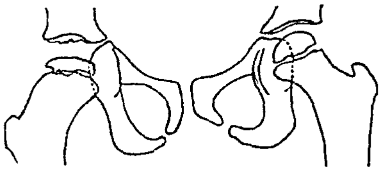

FIG. 1.—Tracing of skiagram of unilateral case of pseudo-coxalgia. Boy aged 5 years.

The position of the limb at rest is usually normal. There is slight wasting of the thigh and buttock, with resulting apparent prominence of the trochanter; some thickening of the neck of the femur, particularly on the inner side, may occasionally be felt; abduction of the hip is markedly limited or obliterated, while flexion remains free, almost, if not quite, to the normal limit; internal rotation and extension may be somewhat limited; at this stage there is no shortening, and rarely does the shortening amount to much. Trendelenburg's sign is usually positive. There is no pain on jarring the trochanter or heel. Skiagraphic examination reveals characteristic appearances; the epiphysis of the head of the femur is flattened from above downwards, irregular in outline and density, or even broken up into fragments; the epiphyseal line is less distinct than it should be, as if invaded by calcified tissue from both epiphysis and neck; the juxta-epiphyseal region of the neck is irregular and fluffy, and there may be clear semi-transparent areas adjacent to the epiphyseal line, more commonly at the upper angle of the neck; on the lower side the neck is thickened; the joint space is not diminished, showing that the cartilaginous head is little, if at all, distorted, but that the changes are

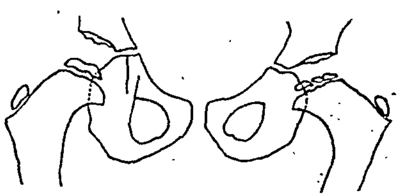

FIG. 2.—Tracing of skiagram of bilateral case of pseudo-coxalgia. Boy aged 6½ years. (Seen with Mr. O. Addison.)

rather in the ossific centre inside it; the pelvis may be asymmetrical, the affected side being slightly the smaller of the two; the acetabulum may show changes in the way of fluffiness and want of definition.

Progress, Treatment, and Ætiology.

The progress of the case is always towards recovery. Abscess formation and other complications seen in true hip disease never occur. Most writers agree in stating that treatment, or entire absence of treatment, has little, if any, effect on the ultimate result. Radiograms taken at intervals for one, two, or even three years show that after a time the ossification of the epiphysis returns to the normal, until at last the hemispherical shape of the ossific centre is restored. Finally, there may be some mushrooming of the head of the femur, so that the appearance would justify the diagnosis of one form of juvenile osteo-arthritis. The limp, usually slow in disappearing, is eventually lost. Spasm of muscles may occasionally be a feature in the early stages, when the diagnosis may be difficult. As a rule the diagnosis is easy.

Although treatment is said to have no effect, it is wiser to order a walking calliper splint to take the weight off the femur, while cases with an unusual amount of pain or spasm must be treated with complete rest and extension for a time. Muirhead Little advises abduction under anæsthesia and fixation in plaster, so that changes in the shape of the head that might limit abduction may be avoided.

As to the nature of the affection nothing definite is known. The theory which receives the greatest amount of support is that trauma produces damage to the blood-supply of the head of the femur, and that the changes in the ossification of the bone are secondary to this damage. Developmental error—as a predisposing if not the sole cause—local infection, and rickets have all been suggested in explanation of the appearances. Tubercle and syphilis can undoubtedly be ruled out of court. Suffice it to say that there are difficulties in the way of accepting the traumatic theory, but the discussion of this subject must be left for a subsequent publication elsewhere. Similar radiographic changes in an epiphysis are met with in other regions of the body.

A NOTE ON

SPIROCHÆTES IN THE ÆTIOLOGY OF CERTAIN PARALYSES.

BY G. SCHUSTER, M.D.,

ASSISTANT PROFESSOR AT THE PSYCHOLOGICAL AND NEUROLOGICAL CLINIC OF THE ROYAL HUNGARIAN UNIVERSITY OF BUDAPEST.

AT the suggestion of Professor E. E. Moravcsik, M.D., I started research in the parasitology and pathological tissues of general paralysis of the insane, at the Psychological and Neurological Clinic of the Royal Hungarian University of Budapest, soon after the publication of Noguchi's researches. The outbreak of war prevented me continuing this work, but I was able to resume it at the end of 1918. I include in this short contribution my more important observations on the presence of spirochætes in the central nervous system, before publishing a longer description of the cases treated in this clinic in view of their parasitological, clinical, and therapeutical applications. I also take the opportunity of reporting an interesting diagnosis in a case of disseminated sclerosis.

Levaditi, Marie, Bunkowsky, Moore before Jahnel, later Hauptmann have shown the presence of spirochætes in large quantities in the cortex of patients suffering from G.P.I. with paroxysms; they regarded the paroxysms as due to mechanical and toxic effects of the sudden increase of spirochætes. During my researches I have noticed that the spirochætes are situated chiefly in the lower strata of the cortex, sometimes in such quantity as to show almost a pure culture. This was noticed not only in cases of G.P.I. with paroxysms, but also in those without. In eight cases of G.P.I. the main colonies were in the boundary of the cortex and the medullary substance, and in the lowest strata of the cortex; this was so, not only when the spirochætes were localised, but when diffused over the whole area of the cortex. It is difficult to say without further research whether the spirochætes are permanently localised in these strata, because their dissemination is prevented by some means, or because the circulatory or microchemical environment is favourable. Some observations convinced me of the pathological and clinical importance of the boundary of the cortex and the medullary substance. In certain cases of disseminated sclerosis the sclerotic spots are mostly on this boundary. I found, as did Siemerling, in an acute and in a chronic case that the disintegration of the medullary sheath was situated underneath the cortex and in the lower boundary of the cortex. In cases of diffuse sclerosis and peraxial sclerosis (Rossolimo, Angyan, Schilder) the spots of disintegration of the medullary sheath were immediately underneath the cortex, also overspreading some areas of the cortex; disintegration of the medullary sheath in the cases of G.P.I. (which were similar to those in disseminated sclerosis) was also to be seen on the boundary of the cortex and medulla, as was shown by Siemerling, Spielmeyer, Borda, and Fischer. These observations show that there are certain places in the central nervous system which have microchemical properties of importance in the ætiology of G.P.I.; in regard to the parasitological aspect the lower strata of the cortex seems to have microchemical affinity with the spirochætes.

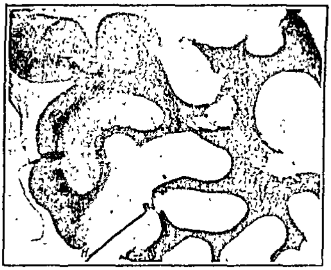

FIG. 1.—Heterotopia in disseminated sclerosis.

The spirochætes appear in largest quantity in this place, and the so-called degenerative forms are mostly in the upper strata of the cortex. In an interesting case of disseminated sclerosis I found fine spirochætes diffusely spread in the upper strata of the cortex. (Figs. 1 and 2.) This diagnosis shows an affinity between disseminated sclerosis and G.P.I. in regard to ætiology; the gold sol reaction of the cerebrospinal fluid is similar in disseminated sclerosis, in G.P.I., and in cerebral syphilis; it is probable that the spirochætes found by Kuhn and Steiner are a similar kind to the *S. pallida*. It was impossible to show spirochætes in the brain of patients suffering from G.P.I. in those cases when 10 per cent. formalin was injected into the brain through the carotids two hours after death. I thought I should be able in this way to fix the spirochætes thoroughly and instantaneously around the veins, but either the formalin stream carried off the spirochætes or they did not happen to be present in that part of the tissue examined. If, indeed, the formalin stream carries off the spirochætes this would be a favourable fact from the therapeutic point of view. We cannot yet judge the results of the carotid injections made by Knauer. It is

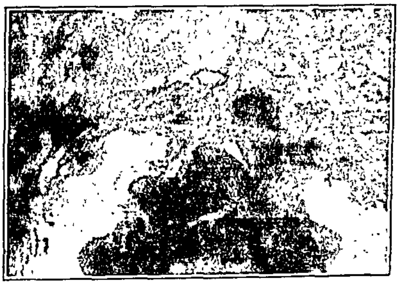

FIG. 2.—Spirochætes in the cortex of a case of disseminated sclerosis.

obvious, however, that one could always discover even dispersed organisms if the central nervous system had not previously been hardened by injection.

Summary.

1. Large quantities of spirochætes are to be found in the central nervous system in cases of G.P.I., even when it runs a simple course without paroxysm. 2. The main colonies of the spirochætes settle in the lowest strata of the cortex, and while increasing in number there they may spread over other areas of the cortex; whilst alterations of the tissue of the cortex may be extensive the alterations of the medullary sheath are most obvious just on the edge of the cortex and medullary sheath. 3. I was able to show fine spirochætes in the lower layers of the cortex in a case of disseminated sclerosis; there seems to be some connexion between disseminated sclerosis and alterations of medullary sheath, because in both cases the result caused by spirochætes is plexiform disintegration of the medullary sheath, of which the site of election is the boundary of the corticular and medullary substance. 4. Formalin injection prevents demonstration of spirochætes in the central nervous system.

I take the opportunity to express my thanks to my chief, Professor Moravcsik, for his kind suggestions and advice.

OBSERVATIONS ON THE USE OF
CITRATED MEDIA.

BY H. C. BROWN, C.I.E., M.B., B.CH. CAMB.,
MAJOR, I.M.S.

(*From the Wellcome Bureau of Scientific Research.*)

CITRATE of soda has for many years been used when collecting samples of blood for cultural tests; the admixture of the blood of an animal with a solution of sodium citrate is also employed in the preparation of blood media. It is naturally important to be certain that the addition of sodium citrate has no restraining influence on the bacteria to be cultivated. Harvey[1] states that the addition of sodium citrate to a nutrient broth tends to inhibit the growth of *B. typhosus*. In a special report[2] of the Medical Research Council it is stated that, as the addition of citrate of soda to human blood tends to prevent the growth of many bacteria, this procedure should not be employed. Rosenthal[3] has used citrate of soda instead of bile when studying the cultural characteristics of the enterococcus.

Addition of Citrate Apparently Favourable to Bacterial Growth.

Whilst working with this organism in a lemco-peptone broth to which 1 per cent. of sodium citrate had been added, I was struck with the great increase in growth compared with that in the uncitrated broth. The citrate used throughout these observations was the ordinary trisodium citrate having a faintly alkaline reaction.

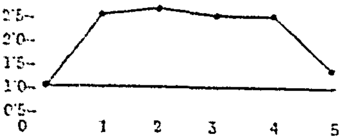

CHART 1.—Cholera, 24 hours. Increase of growth in citrated broth.

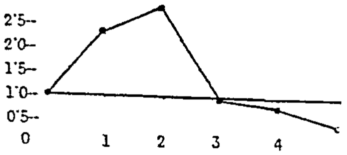

CHART 2.—*B. cloacæ*, 24 hours. Showing maximum growth in 2% citrated lemco broth, P_h 7·6.

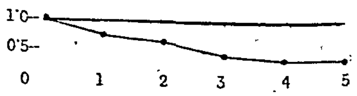

CHART 3.—*B. typhosus*, 24 hours. Showing inhibition of growth.

NOTE.—The horizontal line in each chart shows the yield of organisms in the control uncitrated broth. The figures 0 to 5 under each chart indicate the percentage of sodium citrate.

Numerous other organisms have been studied in this way, and it was found that although citrated broth exerted a distinctly inhibitory action on the growth of the majority of organisms, certain other organisms produced a considerably heavier growth in citrated than in the control broth. A list of the organisms in which the growth is inhibited or enhanced in citrated broth is shown in the Appendix. It might naturally be assumed that the addition of citrate of soda to a medium had so altered the reaction of the medium as to make it more favourable to the growth of certain organisms.

Method of Investigation.

In order to investigate whether this surmise was correct, a batch of broth was taken and divided into two parts, one being kept as the control, the other portions of the remainder being citrated by the addition of 1, 2, 3, 4, and 5 per cent. citrate of soda. The samples were tubed in 10 c.cm. quantities. The P_h of the original broth was found to be 7·3, and that of each of the citrated samples 7·4; after autoclaving for 20 minutes at 115° C. the P_h of the uncitrated was 7·4, and each of the samples of citrated broth was also 7·4. Tubes, each containing 10 c.cm., having been sown with one loopful of a 48 hours' culture of cholera, were incubated at 37° C., and although the initial reaction of the medium was the same in each case, the growth in the citrated tubes was considerably heavier than in the control broth. In each case smear preparations were made from the cultures and stained by Gram's method in order to exclude the possibility of any error due to contamination. (See Charts 1 to 3.)

Determination of Change in Citrate of Soda.

The next point to be determined is whether any change has taken place in the citrate of soda by the growth of such organisms as cholera and *B. cloacæ*. This is best elucidated by the application of the following simple chemical test. If a 10 c.cm. sample of 1 per cent. citrated broth is taken and an equal volume of a saturated aqueous solution of lead acetate is added, a flocculent white precipitate is produced, which gradually settles; after 48 hours the precipitate occupies a height of approximately one-quarter of the total height of the fluid in the tube, whereas in the case of a 48 hours' culture of cholera, in the same medium, the precipitate only occupies a height of approximately one-eighteenth of the total height of fluid. Presumably what has happened is that the sodium citrate, in the case of the V. cholera culture, has broken up, and consequently only a partial precipitation takes place on the addition of the lead acetate. This effect may be shown rapidly by centrifuging the tubes.

When an organism such as *B. coli communis* is grown in 1 per cent. citrated broth for 48 hours and is treated in this way, the precipitate is as abundant as in the tube containing sterile citrated broth. This is well shown in Fig. B, and when this is compared with Fig. A we see that a heavy precipitate on the addition of lead acetate is produced in the case of those organisms of which the growth is inhibited by the addition of citrate of soda. The addition of lead acetate to a citrated broth culture of an organism provides further evidence of the differential peculiarities of certain organisms when grown on citrated media.

Another point of interest with regard to citrated fluid media is that certain organisms are capable of producing gas when grown in this medium, without the addition of any carbohydrate, for 72 hours or more. So far I have only been able to demonstrate gas formation with *B. pneumoniæ*, Friedländer, *B. cloacæ*, and *B. paratyphosus C.*, and in the case of these organisms no gas was produced in the control broth which contained no citrate.

Growth in Solid Media.

So far the effect of growing organisms in citrated fluid media has been considered, but when solid media are citrated in a similar manner the same holds good. If two samples of nutrient agar are taken, and one portion is citrated to 1 per cent., and then both samples are brought to the same P_h, it will be found that if equal amounts of a broth culture are thoroughly spread over each agar slope the yield of cholera after 24 hours' incubation per square centimetre of solid medium is considerably greater in the case of the citrated than in the control medium.

---

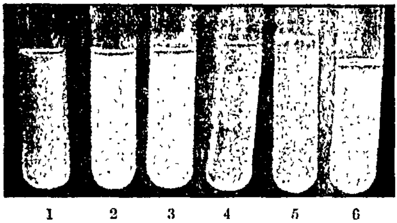
[3] C. R. Soc. Biol., 1917, vol. lxxx., p. 856.

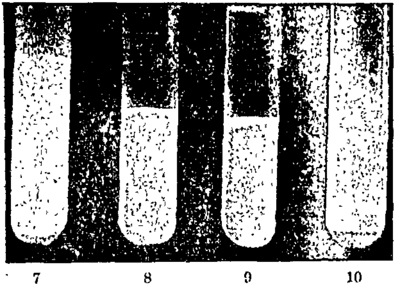
When one comes to study the effect of growing cholera and other cholera vibrios on citrated media the difference between the growth of cholera and those of the vibrios of Metchnikoff and Finkler Prior is very striking, for the growth of the two latter is markedly inhibited by citrate, whereas that of cholera, as already mentioned, is greatly enhanced. Other organisms, however, such as the El Tor vibrio, and paracholera A and B (Mackie and Storer), also vibrios K, Belah, and Ferrest (Mackie) all show a greatly increased growth in citrated broth, and cannot therefore be distinguished in this way from the true cholera vibrio. This fact is specially interesting in that these organisms are more closely allied to the true cholera vibrio than are the vibrios of Metchnikoff and Finkler Prior. In the case of the paratyphoid bacilli I have found that the growth of *B. paratyphosus A* is inhibited in citrated media, whereas that of three strains of *B. paratyphosus B* and also *B. paratyphosus C* is enhanced. The dissociation of the citrate in the case of *B. paratyphosus B* and *C* is clearly demonstrated on the addition of lead acetate, and forms a means of discriminating between *B. paratyphosus A* on the one hand and *B* and *C* on the other, for in the case of the two latter organisms the amount of the lead acetate is considerably less than in the case of *B. paratyphosus A*.

FIG. A.



1. Enterococcus, ordinary broth. 2. Enterococcus, citrated broth. 3. Bacillus coli, ordinary broth. 4. Bacillus coli, citrated broth. 5. Cholera, ordinary broth. 6. Cholera, citrated broth.

FIG. B.



7. Enterococcus, citrated broth. 8. Bacillus coli, citrated broth. 9. Control, citrated broth. 10. Cholera, citrated broth.

Gas formation in a citrated broth after 48 hours in the case of *B. paratyphosus C* appears clearly to differentiate this organism from *B. paratyphosus A* and *B*. Similarly, certain types of intestinal streptococci can be differentiated from others by their behaviour in citrated media, and I have found the test useful in the case of certain unclassified organisms isolated from rats.

The majority of these observations have been conducted with a 1 per cent. citrated broth, but it is probable that a broth citrated to 2 per cent. would have given still more striking results. As regards the length of time of incubation necessary to secure the best results, I am of opinion that 48 hours is probably the optimum, as I have noticed on more than one occasion that when the tubes are incubated for shorter intervals there is apparently, first of all, a slight retardation of the growth in the citrated broth before the enhancement occurs. The terminal hydrogen-ion concentration of citrated and uncitrated cultures may possibly throw further light on the matter, but so far I have not investigated this point. No apparent dissociation of citrate takes place when citrated media are subjected on more than one occasion to high pressure sterilisation; it is thus a medium easy to prepare.

Conclusions.

1. The effect of the addition of citrate of soda to media is that, whilst it inhibits the growth of some organisms, it produces an increase in the growth of other organisms.
2. This increase in growth is not caused by any alteration in the reaction of the medium due to the addition of citrate.
3. The dissociation of the sodium citrate by certain organisms can be well demonstrated by the addition of lead acetate to a 48 hours' culture.
4. Certain organisms are capable of producing gas in simple citrate fluid media.
5. Citrated medium forms an easy means of differentiating the true cholera vibrio from certain other vibrios, also *B. paratyphosus A* from *B. paratyphosus B* and *C*, and certain types of *Streptococcus fæcalis* from others.
6. The addition of citrate of soda to nutrient media should prove useful in the large scale production of cholera vaccine, provided that the antigenic power of the vaccine is not in any way affected.
7. Citrated media can be autoclaved on more than one occasion without affecting their cultural characteristics.

I am much indebted to the Curator of the National Collection of Type Cultures at the Lister Institute for his courtesy in supplying me with the majority of the cultures used in these preliminary observations, also to Captain S. R. Douglas and Dr. White Robertson for the strains of *Streptococcus fæcalis*.

Note.—Since writing this paper I have found a reference to the work of Altobelli in the *Bulletin de l'Institut Pasteur*, 1915, Vol. XIII, p. 133, in which attention is drawn to the fact that certain organisms, more especially *B. paratyphosus B*, are capable of attacking malates, tartrates, and citrates. The original paper is not available, and in the above abstract no mention is made of the enhancement or inhibition of growth of certain organisms or of gas formation.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

WAR SECTION.

A MEETING of this section of the Royal Society of Medicine was held on Dec. 13th, 1920, with the President in the chair.

Lieutenant-Commander E. L. ATKINSON, D.S.O., R.N., read a paper on

Snow-blindness,

based on his experiences in the Antarctic, 1911–13, in the winter campaign in France in 1916 to 1917, and at the Northern Russian Front in 1919. He considered that from the nature of its causation two different sets of symptoms result. 1. Selective reflection of violet and ultra-violet rays from the sun at maximum altitude at midday. This is intensified by the excessive illumination, the light being 1¼, judged by actinometer time. The number of the rays striking the eye is increased owing to the countless ice-crystals forming a perfect distributing surface. He contrasted this effect, if the surface were a perfect reflecting surface when there would then be no change in the intensity of illumination with the change in altitude of the sun. Fifteen minutes of such a day will cause snow-blindness, the symptoms being photophobia, lacrymation, chemosis, with slight hyperæmia of the retina, and later small corneal ulcers. The symptoms come on rapidly, especially on entering a tent where a primus stove is burning. Recovery is the rule. 2. The second class is complicated by diplopia, probably due to excessive strain on the internal and external ocular muscles. With ice-crystals falling the light is so diffused that it comes from every point. There is thus no contrast, and the strain on the visual apparatus is continuous and exceptional. The light value by actinometer time in these days varies from 2 to 12. Photophobia, lacrymation, and chemosis are less and there is no retinal change, and the symptoms do not usually develop for 24 to 48 hours. Hemisine 1 in 1000 is painless and the most efficient remedy. Prevention is assured by efficient glasses, which will give good contrast and cut out the violet end of the spectrum. Both theory and experience indicate that red and dark amber glasses are the best. That altitude of the sun was a very important factor was shown whilst crossing the Beardmore glacier in the Antarctic summer when the sun was always above the horizon. When travelling by night no snow-blindness occurred, while when travelling by day nearly everyone became affected.

Discussion.

Mr. G. E. GASK said that his only experience of snow-blindness was amongst the Swiss Alps, where it occasionally proved a great inconvenience to mountain climbers. The symptoms were conjunctivitis, chemosis, and swelling of lids. There was no retinal blindness. Twenty years ago black glasses alone were used, but these were found to shut out too much light, so as to render crossing glaciers or difficult climbing impracticable. Now deep green or amber glasses were used. If glasses were not available a certain limited protection was afforded by darking the lids and face with burnt cork. Snow-blindness might occur during a snow-storm with complete absence of direct sunlight.

Mr. A. W. ORMOND did not consider that snow-blindness was entirely due to ultra-violet rays, as the cornea and lens stop all such rays from getting through to the retina. The results appear to be secondary to the effect on conjunctiva and cornea. Snow-blindness was probably commonest as the result of exposure in a haze. He suggested that Sir William Crookes's glasses were the most satisfactory.

Mr. J. H. FISHER considered that the superficial conditions of conjunctivitis and keratitis were undoubtedly produced by actinic rays, and that Crookes's No. 2 glasses would probably be more satisfactory than No. 1. A missionary amongst the Canadian Esquimaux had informed him that these people suffered greatly from snow-blindness, and asked his advice as to preventive measures. He had recommended rose-tinted glasses, which the Esquimaux should fit into leather goggles so as to exclude lateral light.

Colonel R. H. ELLIOT considered that the scotomata were due to light rays, and that it was most important to cut off lateral light.

SECTION OF ELECTRO-THERAPEUTICS.

AT a meeting of this Section of the Royal Society of Medicine on Dec. 17th, Mr. S. GILBERT SCOTT, the President, in the chair, Dr. REGINALD MORTON related his impressions gained during a recent visit to the Frauenklinik at Erlangen in connexion with a

System of X Ray Treatment of Uterine Carcinoma

evolved there under Professors L. Seitz and H. Wintz. Some years ago Dr. Wintz, in the effort to improve the results of surgical treatment for uterine carcinoma, experimented with radio-active materials, especially radium. This being too local in its action, he then proceeded to use the X rays in combination, with some improvement. The next step was the development of apparatus and X ray tubes capable of giving a more or less continuous output of rays of a penetration and intensity such as had never before been available for practical work. A specially designed coil working continuously at a normal sparking distance of 16 inches is used to excite the tubes. The latter are of the usual "gas" type, also specially constructed to work at this resistance of 16 inches of air. A very ingenious automatic regenerator keeps the vacuum constant within very narrow limits, and the anticathode is worked at the constant temperature of boiling water. A zinc filter is used having an absorption equivalent to 12 mm. of aluminium. Every tube is standardised and frequently re-calibrated so as to conform to one of the basic principles of the system—the use of a radiation as nearly constant as is humanly possible. Working under the standard conditions the unit skin dose—the amount normal skin will stand just short of injury—will be given in approximately 35 minutes, at the normal focal-skin distance of 23 c.cm. There will be reddening of the exposed patch in from 4 to 8 days and tanning in from 3 to 4 weeks, but no destruction of normal tissue. Taking this unit skin dose as 100, it has been found that a cancerous growth requires 110 per cent. of this to ensure its destruction. Sarcoma requires only 80 per cent. and tuberculous glands and joints respond very favourably to a 50 per cent. dose. A 90 per cent. dose applied to a cancerous growth paralyses it, so to speak, and causes it to shrink, but it is not certainly destroyed and may recur; but if only a 40 per cent. dose is given it acts as a strong stimulant, with perhaps rapid increase in size and possibly serious or even fatal results. This brings us to another of the fundamental principles of the system, that the full cancer dose must be given on the one day. Another important principle is that every case and every dose has to be considered individually—accurately calculated and accurately administered, necessitating full anatomical and topographical knowledge. In a case of uterine carcinoma, for instance, it is found that when the unit skin dose is given over the symphysis, as above described, only about 18 per cent. of this reaches the cervix, dispersion and absorption accounting for the loss of approximately 82 per cent. Consequently further doses are necessary, using six ports of entry for thin subjects and a seventh directed against the vulva for those with thick abdominal walls. Six weeks later one parametrium is attacked, the other being done after 14 weeks. Superficial carcinomata are treated with the tube placed from 70 cm. to 100 cm. from the surface, the exposure varying from 5 to 10 or 11 hours. This is necessary to get even irradiation, since we have but one port of entry under such circumstances; the application is to be repeated after six weeks. The supra-clavicular and axillary regions receive special exposures at the first sitting. Usually the patients are not disturbed during these long sittings and are encouraged to sleep. If there is any restlessness a dose of omnopon or other sedative is useful.

With regard to results, of 24 cases of uterine carcinoma treated by the X rays alone during the year 1918, 20 at the present moment are quite well and leading normal lives, being at least clinically cured and free from any sign of carcinoma, local or general. Approximately equal success has attended the treatment of mammary carcinoma. If there is a large mass of cancerous tissue it should be removed by operation first, but if small it may be attacked at once with very good prospects of success. 75 per cent. of the cases of mammary carcinoma treated in the year 1917 by the X rays and without preliminary operation are now clinically cured.

Dr. **LOUISA MARTINDALE** (Brighton) read a paper on the *Treatment of Uterine Fibroids by means of powerful* deep irradiation through suitable screens on the Fribourg method, a procedure that has been before the profession for several years, and one that gives good results.

Dr. H. G. **ADAMSON** (London) spoke of the use of the X rays in dermatology, making special reference to the treatment of ringworm and pruritus. He also laid stress on the necessity for accuracy in dosage, advocating the method of measurement elaborated by Sabouraud and Noire as being the most reliable for the treatment of skin diseases at least.

The **PRESIDENT**, Dr. **EARDLEY HOLLAND** (London), Dr. J. R. **RIDDELL** (Glasgow), and Dr. R. W. A. **SALMOND** (London) also took part in the discussion.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AN ordinary meeting of this society was held on Dec. 17th, 1920, at 1, Upper Montague-street, W.C., Dr. F. E. **FREMANTLE**, M.P., the President, being in the chair, when Professor H. R. **KENWOOD** delivered a presidential address on

The Work of the Navy, Army, and R.A.F. Group within the Society.

He pointed out that the health services of the fighting forces and of the civil community learnt much from each other during the war; more particularly was the civilian community the richer by the experience, and one object of the Group should be to assist in the utilisation of this knowledge.

The Great War, he continued, witnessed an unprecedentedly full application of the ancient axiom that "prevention is better than cure." There was no axiom more generally accepted and more seldom practised by the individual; and so, foremost in our programme must be the endeavour to secure the goodwill and intelligent coöperation of the rank and file—be they fighters or workers—in the prevention of disease. It is impossible to overstate the value of judicious educational health propaganda work. The time for this is propitious; for the Great War trained and disciplined the populace through their war service and experiences, and it must have uplifted them to a higher level of common aim. Given satisfactory feeding and clothing *homo sapiens* need suffer but little from environment where there is knowledge of, and concern for, the simple rules of healthy living. The environment of the soldier, bad as it often was in trenches and billets during the war, was responsible for little sickness (thanks to good feeding and clothing, sanitary supervision, and discipline), save that due to vermin. General Beveridge had told them that some 50 per cent. of the total sick admissions resulted from disease caused by lack of personal cleanliness and the presence of vermin. There could be no doubt that much more could be done by a well-organised coöperation with the civil authorities to keep our fighting forces freer from vermin, and so to supplement and aid the Service provisions to this end.

Professor Kenwood then dealt with the case which the Great War established for the better spacing of troops in tents, huts, billets. and barracks. He pointed out that the greatest hygienic step ever undertaken in connexion with the army and navy, as proved by sickness and mortality returns, was the provision of additional cubic space and improved ventilation in barracks, and this was introduced many years ago. If the conditions here could be further improved (and there is room for this) it would immensely diminish sickness and promote physical fitness. Increased spacing, he said, meant money; better ventilation meant some difficult education and training of the men; but there would be a big balance on the credit side of the account—even in terms of *£ s. d.* He next referred to certain diseases, notably influenza, which need organised research on a comprehensive scale in order to study their behaviour in the mass. With reference to the course of epidemics, he was satisfied that the lack of susceptible population was not the main cause of their cessation.

In the Great War, he said, preventive inoculations were practised to an unprecedented degree, and death in many forms was thereby prevented to a proportionate extent. Is our civil community to benefit more fully from this experience? He next discussed some respects in which coöperation should be developed between the civil public health staffs and the service sanitary staffs, and the advantages and economy that would thereby result. In connexion with the Territorial Forces this coöperation should be developed to its maximum extent, by making the fullest use of the local knowledge and experience and of existing civil services and provisions, always with due regard to the needs of training and the circumstances of war. The necessity for devising fuller measures for the mutual protection of the civil and military population against the spread of venereal disease was impressed during the war, and here was an enormous wastage in the fighting efficients which could and must be reduced in the future. We learnt from the army to meet many sanitary requirements by means of simple and inexpensive appliances, fever hospitals, &c. Is the civil community going to profit from this lesson. The extravagant cost of many civil provisions has had the effect of limiting their adoption by smaller communities where they are often greatly needed. Cannot a happy mean be established between the two extremes?

Professor Kenwood concluded by expressing the hope that occasionally the Group would be invited by the Directors of the various Medical Services to coöperate in some matter of research in which they might be judged capable of rendering useful assistance. Such help would always be done in a spirit of loyal comradeship and with the sole object of rendering assistance to those who are in the responsible position of advising upon and directing the health provisions of the Services.

Discussion.

Professor **JOHN ROBERTSON**, M.O.H. Birmingham, drew attention to the great difference between conditions in peace and war time, and to the way in which the best laid plans in time of peace often go to pieces in war. Medical officers in Territorial units would need the direction of officers familiar with war conditions. In regard to the sanitary conduct of troops it was wise to expect nothing from the men but what they were actually compelled to do. He had been appalled at the lack of cleanly habits in the men. To encourage good ventilation they must be provided with blankets and proper means of warming. It ought to be possible to prevent vermin infestation in all conditions, and there should be a regular weekly issue of clean clothing. He mentioned the importance of proper spacing of individuals in schools and hutments, and said that he thought that an 8 ft. distance between man and man in tents would have almost prevented the spread of cerebrospinal fever. Young officers, he added, must be taught to keep to proper sanitary standards, and the reasons should be explained to them. The available information as to sanitary matters in the war ought to be recorded and collated for future use.

Professor R. St. G. S. **BOND**, Naval Medical College, Greenwich, said that no one appreciated the Presidential Address more than the naval members. The problem of air-space, ventilation, and spacing was of great importance on warships, and was accentuated by the crowding of extra men on board in the war. Diseases of respiration were prevalent, and influenza was very bad on ships during the outbreak. Before the war the medical officer on a ship had to act as medical officer of health, even if he lacked proper training. During the war a naval sanitary service was founded. Naval health officers had since been appointed at some of the principal ports, and it was hoped that the service would be further extended. Money was the difficulty.

Major-General Sir W. **MACPHERSON** said that the Group constituted a liaison between medical officers of health and the medical officers of the Services. At the early stages of the war local medical officers of health gave great assistance in connexion with billets. One of the greatest achievements of the war was the work of the sanitary sections in France. The French were astonished at the perfection of our latrine arrangements in the front line, and later imitated them. General Macpherson emphasised the importance of education in sanitary matters and mentioned that in some details, such as the disposal of refuse and excreta, the civil authorities could learn from the military.

Dr. G. A. AUDEN, school medical officer, Birmingham, said that the importance of sanitation must be inculcated in the combatant officers. He was surprised at the way in which even public school men relapsed into hopelessly insanitary habits on active service.

Squadron Leader A. GRANT, R.A.F., mentioned the importance of coöperation between civil and service medical officers, and referred to a recent outbreak of cerebro-spinal fever, which was only recognised after an R.A.F. man had become involved in it. Infectious conditions were often introduced into units by men who acquired them when on leave. Difficulties arose from the absence of facilities for the prophylactic treatment of venereal diseases for men on leave.

Professor P. S. LELEAN, R.A.M. College, in connexion with the question of spacing, stated that Petri dishes placed in the proximity of men whose throats had been sprayed with *B. prodigiosus*, showed numerous small colonies at distances of 2 and 4 feet, fewer at 6 feet, and at 8 feet they were beyond the reach of infection by fine spray and only received occasional massive infection from droplets. He paid a tribute to the work of officers of sanitary sections, including architects and surveyors with medical men. He remarked on the badness of the water-supply in some rural districts.

Dr. HERBERT JONES, M.O.H., Herefordshire combined districts, referred to the initiation of the sanitary service, which was intended by Sir Alfred Keogh to enlist the services of the principal civilian medical officers of health.—Dr. W. J. SLOAN, Assistant School M.O., L.C.C., spoke of the exactness with which the carrier rate in cerebro-spinal fever corresponded with the spacing of the men.—Dr. HUTCHINSON WOOD, M.O.H., Biggleswade U.D.C., said that the sanitary education of the commanding officer was necessary, as well as of the rank and file.—Dr. R. H. WILSHAW, M.O.H., Worthing, suggested that the sanitation of camp hutments could be very much improved by following the lines of sanatorium buildings.—Dr. C. SANDERS, M.O.H., West Ham, inquired whether the meeting could not do something to hasten the production of the sanitary history of the war. It was ten years before that of the American War was published.

The PRESIDENT said that the war had required adaptation on the spot to all sorts of conditions previously unknown, such as strange climates and new infections. He instanced the way in which malaria had been dealt with by medical officers who had never before come across it. There had been remarkable opportunities for preventive work owing to the possibilities of complete control over the activities of the men, and of obtaining comprehensive statistics and returns. The generation which had fought and the next generation would yet benefit from the habits of hygiene inculcated during the war. He predicted a brilliant future for the new Group.

Professor KENWOOD, in replying, indicated the following items of work for the Group in the immediate future: (1) education and health propaganda; (2) coöperative measures for safeguarding the mutual interests of the civil and military medical officers; (3) advising the civil authorities as to the adaptation of military sanitary measures to civil conditions; (4) camp hygiene and sanitation (sites, water-supply, hutment types, &c.). He said that the honorary secretary of the Group (Dr. W. N. W. Kennedy, Town Hall, Croydon) would be pleased to receive the names of any naval, military, or R.A.F. medical officers desirous of joining the Group.

Thirty-one new members of the society were elected at the meeting.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

Exhibition of Cases and Specimens.

A WELL-ATTENDED meeting of this society took place on Dec. 17th, 1920, at the laboratories of the London School of Tropical Medicine, 23, Endsleigh-gardens, N.W., with Professor W. J. R. SIMPSON, the President, in the chair.

The following demonstrations were given:—

Sir JAMES CANTLIE showed a male patient from Baghdad suffering from "Baghdad Ulcer" on the finger of several months' duration.

Dr. H. S. STANNUS: Sections and photographs of examples of malignant disease in African natives. (1) Spindle-celled sarcoma of the testicle with secondary deposits in each orbit; (2) carcinoma of the thyroid and liver; (3) malignant parotid tumour. He referred to the comparative infrequency of malignant disease among natives, which, as the result of 15 years' experience in Central Africa, he thought was not as rare as generally supposed.

Colonel S. P. JAMES, I.M.S.: Specimens illustrating true indigenous malaria in England. Stained blood-films, showing *Plasmodium vivax* from cases of benign tertian fever in children aged 5 and 13, in October, 1919, and August, 1920, coming from Queenborough and Isle of Grain, Kent, and *Plasmodium falciparum* from a case of malignant subtertian fever in a girl of 18 at Sheerness; slide preparation of stomach of *Anopheles maculipennis* fed on a case of indigenous malaria and showing many zygotes. A map of England was shown giving the geographical distribution of cases of malaria in 1915–17, and in 1919.

Surgeon Rear-Admiral P. W. BASSETT-SMITH: Trypanosome Infection of Fœtus—specimens of *T. gambiense* in the spleen and liver of the guinea-pig fœtus and of *T. rhodesiense* in the liver of the rat as the result of maternal infection. Transmission of trypanosome infection to the healthy young guinea-pig by suckling from the infected female had been reported, but his experiments in this direction had proved negative.

Dr. A. C. STEVENSON: Extravascular Distribution of Trypanosomes in Tissues—sections (1) of the choroid-plexus, kidney, and stomach of a guinea-pig, showing presence of *T. nigeriense* in the areolar tissues; (2) of the labyrinth of the ear, heart muscle, and mediastinal lymph gland showing *T. rhodesiense* infection of the areolar tissues.

Major H. C. BROWN, I.M.S.: (1) Standardisation of Bacterial Suspensions by Opacity for estimation of weight and number of organisms in vaccines, aided by calculated proportional tables of the required vaccinal strengths; (2) the value of citration of liquid culture-media by sodium citrate (1 per cent.) for the purpose of retarding or augmenting bacterial growth—e.g., in particular the inhibition of *Paratyphosus A*, and increasing the development of *Paratyphosus B* and *C*.

Dr. ANDREW BALFOUR: Models of Fruits and Foodstuffs from India.

Dr. P. MANSON-BAHR: 1. Amœbic Dysentery. Illustration of the value of sigmoidoscopic examination in diagnosis, by drawings of the appearance of the ulcerated rectal wall and of scrapings obtained through the sigmoidoscope showing *E. histolytica* cysts in large numbers. 2. Kala-azar. (*a*) Persistence of *Leishmania donovani* in the bone marrow in a patient who died from intestinal complications. (*b*) Section of liver showing periportal cirrhosis and perihepatitis, associated with ascites and perisplenitis. 3. Malignant subtertian malaria in a Palestine case. Blood films showing multiple ring forms of the parasite. Sections of liver and heart muscle exhibiting many parasites in the blood-vessels. 4. Stomach of infected *A. maculipennis*, showing presence of sporozoites.

Lieutenant-Colonel A. ALCOCK: Specimens of—(1) the tick *Dermacentor venustus*, vector of Rocky Mountain fever; (2) British anopheline species, *A. bifurcatus* and larvæ, *A. maculipennis*, *A. plumbeus*; (3) *Stegomyia fasciata*, living and microscopical specimens of larvæ;

(4) fruit mite (*Carpoglyphus passularum*) from case of grocer's itch; (5) flea (*Pulex irritans*), showing the anatomy of the alimentary tract—in particular the mouth apparatus and proventriculus.

Dr. J. G. THOMSON: Preparations of Leishmania Infections. (1) Kala-azar. *Leishmania donovani* in smear from spleen pulp and section of spleen; living and stained specimens of the parasite obtained by N.N.N. (Novy-MacNeal-Nicolle) method of culture. (2) Oriental sore. *Leishmania tropica* in section of the granuloma and in living and stained preparation from culture by N.N.N. method.

Professor R. T. LEIPER: Helminthological Preparations. (1) *Dipylidium caninum* from a female patient in South Africa; (2) shells of *Bithynia striatula*, intermediary mollusc host of *Clonorchis sinensis* (human liver fluke); (3) cercaria of *Clonorchis sinensis* on a fish scale; (4) abnormal branching of *Hymenolepis*; (5) cystercercoids expelled from body cavity of *Cypris* and *Cyclops*; (6) ova of:—*Clonorchis sinensis*; *Fasciolopsis buskii* and *Heterophyes heterophyes* (intestinal flukes); *Schistosoma japonicum*; *Paragonimus westermanni* (lung fluke); *Oxyuris vermicularis* showing the inner shell; *Ascaris lumbricoides*; *Ankylostoma duodenale* (from a cat experimentally infected).

Dr. G. C. LOW: Human Blood Filariæ. Fresh blood-film preparation showing the living embryo of *F. bancrofti* (*nocturna*); stained preparations differentiating embryos of *F. bancrofti* and *loa* (*diurna*).

Dr. E. ATKIN and Mr. A. BACOT: Rickettsia of Typhus and Trench Fever. (1) Typhus. Specimens of *Pediculus corporis* and *capitis* fed on human case of typhus, showing *R. prowazeki* in coccoid and bacillary forms, also in smears of gut contents, and in smears of *P. capitis* fed on typhus-infected monkey; sections of brain of guinea-pig infected with typhus show cell proliferation about the blood-vessels. (2) Trench fever. Smears of secretion and section of gut of *P. corporis* showing *Rickettsia quintana*. (3) Rickettsia bodies in gut smear of the tick *Dermacentor venustus* vector of Rocky Mountain fever. (4) *R. lectularia* of bed-bug. (5) *R. melophagi* in smears of ovary and kidney of sheep.

Lieutenant-Colonel G. E. F. STAMMERS, R.A.M.C.: Spirochætal Jaundice in the Guinea-pig. Cadaver of infected guinea-pig showing pleural and peritoneal hæmorrhages. Sections of lung of guinea-pig, infected from the rat, and of the liver of rat, both showing the presence of *Leptospira*.

Colonel CLAYTON LANE, I.M.S.: Demonstration of Levitation Method for Concentration of Ankylostome Eggs in Fæces.

Sir STEWART STOCKMAN: Piroplasmosis of Domestic Animals.

Mr. J. T. EDWARDS: Pathological Specimens of veterinary interest. Inflammation of ileum of ox in Johne's disease; enlargement of spleen due to Hodgkin's disease in a dog; aorta of horse showing verminous penetration by *Strongylus vulgaris*; lung of ox showing consolidation in hæmorrhagic septicæmia; ulcerative colitis due to infection by *B. necrophorus* in swine fever; swine erysipelas shown by typical skin lesions and chronic vegetative endocarditis; diphtheria of tongue and lips due to infection by *B. necrophorus* in a calf; tongue of calf in foot-and-mouth disease, &c.

Dr. A. CASTELLANI: Some Tropical Mycoses. (1) Bronchomycosis due to *Monilia krusei*, shown in films from sputum and in culture; (2) *Tinea imbricata* of skin due to *Endodermophyton indicum*; (3) acladiosis—ulcers of leg—caused by *Acladium castellani-pinoyi* ((2) and (3) shown in photographs and cultures); (4) mycelial fungus in urine from a case of cystitis.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING of the Pathological Section was held on Dec. 2nd, with Dr. J. E. GEMMELL, the President, in the chair, when Professor G. J. ADAMI read a paper on

The Pathology of Influenza.

He described the attempt to find a common lesion for the successive stages of pre-pandemic purulent bronchitis, pandemic pneumonia, and the hæmorrhagic pulmonary œdema characteristic of the late pandemic of influenza, and to distinguish those lesions due to the primary causative agent from those due to the secondary invaders. He said it was the generally accepted view that the influenza epidemic started in May of 1918 and was followed by a much more serious epidemic in the autumn, but he did not think this view correct. As early as 1916 and the spring of 1917, Hammond, Rolland, and Shaw described in THE LANCET[1] a series of cases of purulent bronchitis in the Etaples area, characterised by a peribronchitis, a destruction of the lining epithelium, a bronchitic and bronchiolitic purulent discharge and all associated with the presence of both the influenza organism and the pneumococcus. In the latter year, 1917, an exactly similar epidemic was noted in the Aldershot area by Dr. Adolphe Abrahams and others.[2] In the same year the American bacteriologists noted a very fatal form of pneumonia following measles. MacCallum showed that the morbid anatomy of the respiratory tract was that of an interstitial pneumonia, an exudate that was not excessively cellular, a destruction of the epithelium of the bronchi, and a microscopic appearance of the bronchioles extremely suggestive of the French and English epidemics. MacCallum found, however, that the chief organisms in this series were a hæmolytic streptococcus and the pneumococcus. The influenza organism was only noted a few times. Then came the great epidemics of 1918. Dr. Adami showed that in the reports from France, Macedonia, Italy, India, and America he was able to trace a common histology and bacteriology. From all areas the disease was ushered in with congestion and suppuration of the upper nasal respiratory tract, and in those reports where these parts had been bacteriologically examined invariably the influenza organism had been recovered. Further, a tracheitis limited to the lower third of the trachea was, perhaps, the greatest common histological factor. He felt sure that whatever may have been the changes due to other organisms, the influenza organism of Pfeiffer, if not the causa causans, was always associated with the disease. In the autumn, however, it was obvious that the virulence of the organism had been raised to an inordinate degree, and he suggested that the absence of pus and the hæmorrhagic œdema and the marked lymphatic dilatation might be explained by negative chemiotaxis. In this connexion Dr. Adami referred to the classical experiments of Metchnikoff on mild and virulent anthrax organisms. Dr. Adami then demonstrated the means whereby the lungs are protected from organisms by the obliquity of the naso-pharynx and the ciliated epithelium, and showed how in influenza this beautiful protective device breaks down.

The discussion was adjourned until the next pathological meeting.

A clinical meeting was held on the afternoon of Dec. 16th, 1920, Dr. J. E. GEMMELL, the President, in the chair.

Dr. FRANCES IVENS read a note on the

Use of Antigonococcal Serum,

indicating briefly the methods used and the results obtained in a series of 30 cases. The patients were, with two exceptions, young married women. Thirteen had no children and nine one only. The cases included 22 of tubal infection, three of endocervicitis, and two of arthritis occurring during pregnancy and the puerperium. *Nicolle* serum had been employed, and was administered in 19 cases subcutaneously, in six into the tubes and peritoneal cavity, and in five vaginal or local applications had been made. To avert anaphylactic shock normal saline solution had been administered simultaneously. All the cases made good immediate recovery and the after-results were strikingly good in the majority of the cases, the least successful being those where the intraperitoneal method had been employed. Dr. Ivens considered that the results warranted further experiments and study, and asked for suggestions respecting the best method of administration in view of the special characters of the organism and the fact that it did not belong to a diffusible group.

Clinical cases were shown by Dr. John Hay, Drs. R. J. M. Buchanan and J. C. Matthews, Dr. H. M. Mitchell, Dr. A. D. Fordyce, Dr. R. Stopford Taylor, Mr. T. Stevenson, Mr. F. J. S. Heaney, Mr. G. C. E. Simpson, Dr. R. W. MacKenna, Mr. T. H. Bickerton, Dr. Murray Bligh, and Mr. R. C. Dun.

Reviews and Notices of Books.

WOMEN AS ARMY SURGEONS.

Being the History of the Women's Hospital Corps in Paris, Wimereux, and Endell-street, September, 1914–October, 1919. By FLORA MURRAY, C.B.E., M.D. London: Hodder and Stoughton. 1920. Pp. 263. 12*s.* 6*d.*

THIS book, besides being a most interesting record of indubitably valuable work, is also a glorification of the women's movement, including the struggle for the suffrage. No medical woman or man can withhold praise from the way in which the Women's Hospital Corps did their work; often, especially in the early days of the war, as at Paris and Wimereux, in conditions of extraordinary difficulty. Lack of transport for the wounded was the curse which afflicted both the French and the British medical service in the early days, and had it not been for the American voluntary fleet of motor ambulances matters would have been even worse than they were. The rapidity with which the women organised their hospital corps and managed to get the hospital in Paris into working order is amazing. The idea was set on foot on August 12th, 1914; on Sept. 14th the W.H.C. left Victoria for Paris, and took up its abode in the Hotel Claridge, where by the evening of Sept. 17th they had 50 beds ready for patients.

Not long after this the unit expanded and opened a hospital at Wimereux, this time under the Royal Army Medical Corps; the Paris hospital was under the French Red Cross. On Jan. 18th, 1915, it was decided to close the hospital in Paris on account of various difficulties, mainly the almost insuperable one of getting enough fuel, and the staff proceeded to Wimereux to join up with the rest of the corps, but in about a month Sir Alfred Keogh offered the corps the charge of a large hospital in London. This was in February, 1915, and by May of that year the hospital in Endell-street, formerly the workhouse of St. Giles, Bloomsbury, was opened, the staff approximating to 180 persons, of whom 21 were men of the R.A.M.C. detachment. The hospital did admirable work, for an account of which we must refer the reader to Dr. Murray's book, where, besides accounts of the professional work carried out, there will be found amusing descriptions of the conflicts with "brass hats" and the War Office. However, the energy and enthusiasm of the staff triumphed over all difficulties, and Endell-street went ahead until October, 1919, when the order went forth that it should be evacuated and closed. Dr. Murray's pride in the W.H.C. shows in every line of her book, but it is pardonable. There is a trifling error on p. 142, where Hildegarde is mentioned as the "famous medicine woman of the third century"; she lived from 1098–1180.

TEXT-BOOK OF TRACHEO-BRONCHOSCOPY.

Technical and Practical. By Sanitätsrat Dr. M. MANN. *Translated by* A. R. MOODIE, M.A., M.D., Ch.B. St. And., F.R.C.S. Edin. London: John Bale, Sons, and Danielsson. 1920. Pp. 292. 31*s.* 6*d.*

THE first part of this treatise, after a short and perfunctory account of the anatomy, is devoted to the technique of the method of direct examination, and begins with a long illustrated list of instruments; though he expresses no opinions in this section, we gather that the author prefers Brünings' apparatus. There follow some useful hints on the introduction of the tube. Dr. Mann favours the sitting position and local anæsthesia, though he mentions that Killian's school has, from the first, considered general anæsthesia a necessary expedient. We cannot, however, agree with the advice implicit in the statement that "when carrying out upper bronchoscopy in an infant, it is sufficient simply to hold it still with the hand." The next section is the most valuable and comprises abstracts of a large number of cases of foreign bodies in the trachea and bronchi, of absorbing interest to the laryngologist; the list is naturally far from complete, and we regret to find so few British cases quoted, although plenty of good work in this field has been done here. The following section deals with bronchoscopy in diseases of the bronchial system. Dr. Mann is disappointed that, in the six years since his book appeared in Germany, there has been an almost complete disappearance of published papers by those who have endeavoured to employ the method in disease of the thorax, either for examination or therapeutic applications. He gives some interesting descriptions of the result of examination in various diseases, but, though he urges physicians to make use of bronchoscopy for purposes of treatment, the results he is able to give are not, so far, very encouraging. There are several good coloured plates of post-mortem specimens, but only one, though an interesting one, of a series of images seen through the bronchoscope. It could be wished that the author had included œsophagoscopy in his survey. Owing to a misapprehension of the original German, Clar's lamp is attributed to "Clarsche," but the translation into rather colloquial English is, on the whole, excellent.

ACCESSORY SINUSES OF THE NOSE.

The Catarrhal and Suppurative Diseases of the Accessory Sinuses of the Nose. By ROSS HALL SKILLERN, M.D., Professor of Laryngology, Post-Graduate School, University of Pennsylvania. London and Philadelphia: J. B. Lippincott Company. 1920. Pp. 418. 30*s.*

THE third edition of this work is practically a reprint of the second, reviewed in our columns early in 1917; it contains several new illustrations and one more page, devoted to a description of Grayson's method of exploratory opening of the sphenoidal sinus with a small hand-burr. The first section treats generally of anatomy, ætiology, symptoms, diagnosis, treatment, and complications; the next four sections deal respectively with the maxillary, frontal, ethmoidal, and sphenoidal sinuses, and there is a final short section on multiple sinusitis. The book is beautifully illustrated and gives a very thorough account of a difficult and complicated subject; it has already proved its value to the rhinologist. The price has been raised from 21*s.* to 30*s.*

LECTURES ON TROPICAL OPHTHALMOLOGY.

Delivered at the London School of Tropical Medicine, by ROBERT HENRY ELLIOT, M.D. Lond., F.R.C.S. Eng., &c. London: Henry Frowde and Hodder and Stoughton. 1920. With 13 illustrations. Pp. 36. 3*s.* 6*d.*

THIS brochure is the skeleton on which the larger work on "Tropical Ophthalmology," reviewed in THE LANCET, Nov. 6th, 1920, was founded. It is a useful introduction to the subject, such as might be expected from Mr. Elliot. In the section on the treatment of the eye complications of tropical diseases there is a warning to the tropical practitioner which, though contained in the larger work, is relatively more prominent in the smaller. It is that in the various conditions for which arsenical and antimonial preparations are used, it is essential that the doctor should "keep vividly before his mind's eye the spectre of optic atrophy."

FORMULAIRE DES MILIEUX DE CULTURE EN MICRO-BIOLOGIE.

By DERIBERE DESGARDES. Paris: Librairie le François. 1921. Pp. 98. Fr.4.

THIS small volume contains a collection of formulas for the preparation of the principal media used in bacteriological laboratories. An almost endless number of media have been described, and the author has perforce to limit his selection to those in general use. The media described are those most favoured in France; some which are favoured in this country are not mentioned—e.g., MacConkey's medium. There is no reference to Levinthal's medium for the cultivation of *B. influenzæ*. These defects are not of importance to the English reader, however. The book can be commended to those who require the information it offers.

ROENTGENOGRAPHICAL TECHNIQUE.

The Principles and Practice of Roentgenographical Technique. By I. SETH HIRSCH, M.D., Director, X Ray Departments, Bellevue, Fordham, Harlem, and Gouverneur Hospitals, New York City. London: H. K. Lewis and Co. 1920. Pp. 241. 60*s.*

DR. Hirsch has had a long experience in teaching radiology, and few are more competent to write such a treatise as this. Knowing so well just what the student requires, he has carefully avoided that which does not matter, while giving plenty of what is necessary to make a successful radiologist. As the title suggests, fundamental principles are what count in the management of apparatus, assistants, and patients, and this idea runs through the whole work consistently. The technical details of many forms of apparatus are frequently a stumbling-block to the beginner, and in such cases the author has introduced a series of large-scale diagrams, serving admirably to clear up difficult points. The chapters on X ray tubes, as well as those on production and measurement of the X rays, and the practical applications of the principles, are particularly good. Fluoroscopy, radiography, postures and positions of the patient are described in detail and illustrated by blocks and diagrams of high quality and ample numbers. Numerous tables add to the value of the work, such as wiring tables, tables of absorption, voltages, exposure, and many others. The subject is a difficult one to undertake and Dr. Hirsch has done it well. There must be very few radiologists who cannot learn something worth knowing from a perusal of this volume; for the beginner it will be invaluable.

THE RADIOGRAPHY OF THE CHEST.

Vol. I., Pulmonary Tuberculosis. By WALKER OVEREND, M.A., M.D. Oxon., B.Sc. Lond. London: William Heinemann, Ltd. 1920. With 99 radiograms and 9 diagrams. Pp. 120. 17*s.* 6*d.*

THIS work is painstaking and well balanced. The author is enthusiastic as to the value of the X ray method in diagnosis, but is yet careful to maintain a sense of proportion between this and the more classical modes of examination, which, after all, have served very well.

This first volume commences with a chapter, illustrated with good radiograms as well as drawings, on the normal chest, and it is lucid and complete, but the author's views on the nature of the branching shadows that make up the pulmonary reticulum are open to comment. He still considers their origin obscure, whereas we were under the impression that the excellent work of K. Dunham had finally settled this question. In dealing with the various types of tuberculous involvement of the lungs the author gives first the usual history, symptoms, and clinical signs, follows on with the X ray appearances, and then contrasts or reconciles the whole as the circumstances permit. It is unnecessary to discuss these chapters in detail; the book must be read and studied in conjunction with the typical radiographs illustrating the various forms of pulmonary tuberculosis.

We think the value of the volume is marred by the adoption of an antiquated classification and nomenclature, as well as by the too free use of a phraseology which, while no doubt academically correct, the average medical man will find cumbersome. None the less Dr. Overend is to be congratulated on the extent and thoroughness of his work, which is a very valuable contribution to a difficult but interesting subject.

MANUEL D'URÉTROSCOPIE.

By ROBERT HENRY and ANDRÉ DEMONCHY. With a preface by Dr. MARION. Paris: Masson et Cie. 1920. With 86 illustrations, including 30 in colours. Pp. 116. Fr.25.

THIS little book gives a general survey of the subject of urethroscopy. A large part of it, more than half the text, is given to description of various urethroscopes and cysto-urethroscopes, and the accessory apparatus is commonly used in conjunction with these. An instrument designed by one of the authors, Demonchy's urethroscope, is described in detail, and in a chapter devoted to a critical examination of all the instruments mentioned it is given first place in order of merit. It resembles Luys's urethroscope in general construction but has a telescope attached. The authors pronounce those urethroscopes which are designed to give dilatation of the canal by air or water to be of little use, even in the examination of the posterior urethra, though they admit some virtues in the various irrigating cysto-urethroscopes. Most of their English readers will differ from them, for in this country aero-urethroscopes are generally used for the anterior urethra and irrigating instruments for the posterior. The latter part of the book contains chapters on the appearances of the normal and abnormal urethra, and on methods of treatment through the urethroscope.

All the illustrations in colour are of the appearances seen in the undilated urethra, which, of course, differ markedly from those obtained when the canal is dilated with air or water during examination.

EARLY EMBRYOLOGY OF THE CHICK.

By BRADLEY M. PATTEN, Assistant Professor of Histology and Embryology, School of Medicine, Western Reserve University. Philadelphia: P. Blakiston's Son and Co. Pp. 167.

THIS book was written to help the student in his early work in courses in vertebrate embryology. It is an admirable little work, interesting and instructive, and the student who brings a little intelligence to bear on his reading cannot fail to advance his knowledge, both of actual fact and of principle, to a considerable extent by its perusal. The descriptions are clear, the format excellent, and the illustrations good and useful. Altogether it is a book to be recommended.

ATLAS OF THE SENSORY CUTANEOUS NERVES.

By WILLIAM IBBOTSON, M.R.C.S., L.R.C.P. London: Scientific Press. 1920. Pp. 25. 7*s.* 6*d.*

THIS little book presents a series of coloured diagrams showing the areas of distribution of the sensory nerves. They are, of course, schematic, with appended explanatory notes. We notice that while the text gives the usual levels the situation of the lumbar enlargement in Fig. 1 does not correspond therewith. We also consider that the distribution of musculo-cutaneous on the palmar surface is perhaps too extensive in Fig. 6, and that the ulnar supply on the dorsum in Fig. 7 might be increased, while the area given over to the musculo-cutaneous of the leg in Fig. 8 is too extensive. The author, moreover, has larger views concerning the posterior primary area in the gluteal region than those generally taught. These, after all, are minor matters, in some way subjects of individual opinion, and hardly detract from the value and utility of this little work.

PSYCHOLOGY OF THE SPECIAL SENSES.

Their Disordered Functions. By ARTHUR F. HURST, M.A., M.D. Oxon., Physician and Neurologist to Guy's Hospital. London: Henry Frowde and Hodder and Stoughton. 1920. Pp. 123. 12*s.* 6*d.*

UNDER this title the Croonian lectures, which were delivered before the Royal College of Physicians of London in June, 1920, have now been published as a book. These lectures were reported in abbreviated form in THE LANCET, and were then the object of editorial comment. They record in permanent shape the valuable work carried out by the author in conjunction with colleagues both before and since the war at Guy's Hospital, and during the war in Lemnos, Salonica, Oxford, Netley, and the Seale Hayne Military Hospital. As a frontispiece to this volume *La Dame Stapart* is reproduced from Carré de Montgeron's "La Vérité des Miracles," depicting a miraculous recovery from hemiplegia, hemianæsthesia, and blindness, after a visit to a tomb in the Chapelle de Ste. Anne at Avernal in 1728.

Autobiography of Sir Charles A. Cameron.

With an Introduction by Sir James H. M. Campbell, P.C., Lord High Chancellor of Ireland. Dublin: Hodges, Figgis, and Co. 1920 Pp. 162. 7*s*. 6*d*.

It is only reasonable to suppose that the reminiscences of a man in his ninetieth year, who is also a medical man, a public analyst, and also an Irishman, will afford interesting reading, and Sir Charles Cameron's book does not disappoint expectation. He was born in 1830 and one of his earliest recollections is talking to an old woman who in her youthful days had been present at, or rather had been but a mile or so away from, the field of Culloden during the battle. He also remarks that although he never saw anyone carried in a sedan chair, yet he knew of two which were to be seen on hire at the Rotunda. He presumes, therefore, that they had not quite ceased to be used at the end of the "thirties." Sedan chairs were in use much later than that date, for the late Sir Moses Montefiore attended a Royal garden party in one not very long before he died (1885), and between 1873 and 1877 an old lady who lived in Windsor always used to come to the Eton College concerts in a sedan chair. Sir Charles Cameron's book is full of delightful stories about all sorts of interesting people, among others Sir William Wilde, the aurist and oculist. Wilde was notorious for his untidy and dirty habits, and Sir Charles Cameron mentions the report that he was refused by Helen Faucit on the ground that he did not keep his hands clean. These same habits of Wilde were the occasion of Father Healy's happiest witticism. Healy was a friend of Cameron, but the latter does not give the story, which is as follows:—Shortly after Wilde had been knighted Healy met one of the Irish Members who had just returned from fulfilling his duties in Parliament. The weather was stormy, and Healy asked his friend what sort of crossing he had had. "Bad," said the M.P.; "the dirtiest night I ever saw." To which Healy gravely replied, "Indeed, it must have been wild."

Another of Cameron's friends was Matthew O'Reilly Dease, who used often to entertain Cameron to dinner at the Reform. Although they were only two, Dease always ordered a magnum of champagne, because, as he rightly said, "Champagne stores better in magnums." We hasten to add that Cameron was moderation itself and that Dease never drank more than one glass. We might go on quoting page after page of the book, but we can only congratulate Sir Charles Cameron on its appearance and recommend our readers to read it. It would be the better in places for revision; for instance, on p. 28 Sir Charles Cameron records, if we mistake not, that his wife was born on Oct. 18th, 1838, while on p. 31 he says that she was born on Oct. 26th, 1839.

Normal Histology.

With Special Reference to the Structure of the Human Body. Twelfth edition. By George A. Piersol, M.D., Sc.D., Professor of Anatomy in the University of Pennsylvania. London and Philadelphia: J. P. Lippincott Company. With 438 illustrations, 88 of which are in colour. 1920. Pp. 418. 21*s*.

Professor Piersol's work will be found to be a thoroughly reliable, well-illustrated, and comprehensive exposition of "Normal Histology." Of the coloured illustrations most are in one colour, light carmine or light bluish hæmatoxylin, or methylene-blue tint. Only a few are in two colours—e.g., developing bone, injected skin, inner ear; and only two or three in more than two colours. Anyone familiar with actual well-prepared microscopic sections will at once agree that the illustrations drawn by the "skilful pencil"—to quote the author's words—of Mr. Louis Schmidt are faithful representations of well-selected, typical histological preparations. Moreover, the magnifying power is stated in each case. There are a few schemata or diagrams only, and no diagrams showing the intricate connexions of the various parts of the central nervous system. There are figures of some parts not usually illustrated in books on histology—e.g., mucous membrane of the maxillary sinus and of the frontal and sphenoidal sinuses. The drawings of the injected sections strike us as particularly accurate, but there are few diagrams to systematise the distribution of the finer blood-vessels such as used to be characteristic of the work of Professor Mall. The text is admirable and ample, and as histology has its place at the beginning of the medical curriculum in the U.S.A., some points on the gross anatomy are added—e.g., on the brain and other organs. In a short appendix a few satisfactory and thoroughly tested methods are given.

Handbook of Mechanical Dentistry.

By J. L. Dudley Buxton. London: J. and A. Churchill. 1920. With 168 illustrations. Pp. 269. 16*s*.

This work does not aim at being an elaborate treatise on mechanical dentistry, but rather a guide to practical work in the surgery and laboratory. The author is clear and concise in his descriptions, and has succeeded in producing a book which should be of considerable help to both student and practitioner. There is a chapter on Dental Metallurgy by Mr. H. Terrey.

The Care of Children.

Fourth edition. By Robert J. Blackham, C.B., D.S.O., M.D., Colonel, late A.M.S. London: Scientific Press. 1920. Pp. 113. 4*s*. 6*d*.

In these days, when new books on child culture are appearing almost every day, there is yet room for Dr. Blackham's small work, a fourth edition of which has been called for. The book has been revised and largely rewritten, a preliminary chapter on "The Child's Mother" having also been added. It is an admirable compendium of all that a mother needs to know, the chapter on communicable diseases, supplemented by an appendix giving in tabular form their main features, being one of the most useful. The book is readable and thoroughly practical, one special feature that calls for notice being the hints given on the care of children in India and abroad generally. Altogether, the volume is one that may be unreservedly recommended to all who have the charge of children.

A Thought Book on the Socratic Method.

Edited by T. Sharper Knowlson. London: T. Werner Laurie. 1920. Pp. 200. 7*s*. 6*d*.

This book belongs to that class which Lamb called βιβλία ἀβιβλία. Mr. Knowlson remarks in his preface that he supposes that "it is the practice of every reader of books to make a more or less careful record of the thoughts that have appealed to him." The Thought Book contains a selection from his own notebook, and the principle of the book is that the reader should ask himself questions about the thoughts which Mr. Knowlson has collected for him, in accordance with a scheme of queries supplied by Mr. Knowlson, and should, in addition, make a collection of thoughts for himself and invent his own questions. We cannot see that keeping a book on these lines has any value, neither can we attach much value to Mr. Knowlson's questions. For example, on p. 43 we have a thought from Ruskin, "All education should be moral first; intellectual secondarily." Mr. Knowlson's first query is, "What is the difference between moral and intellectual education?" Anyone with a grain of intelligence would surely know the answer to this without having to think it over and write it down. As for Mr. Knowlson's method being Socratic, socratism does not consist merely in asking questions, its essence is the way in which the questions were asked and the position to which they lured the person questioned. If Mr. Knowlson will read Book IV. of Xenophon's Memorabilia he will get a good idea of what the Socratic method really was. To our minds anyone who followed Mr. Knowlson would rapidly become similar to the philosopher described by Sir George Trevelyan, who used to wander about asking "Why are we created? Whither do we tend? Have we an inner consciousness?" till all his friends when they saw him in the distance used to say, "Why was Thompkins created? Is he tending this way? Has he an inner consciousness that he is a bore?"

GRIFFIN'S CENTENARY VOLUME, 1920.

THE publishing house of Messrs. Charles Griffin and Co., 12, Exeter-street, London, produced at the close of last year a sumptuous centenary volume in which is detailed the history of the firm from its establishment in Glasgow in the year 1820. The name of the house has long been associated with the production of technological books and scientific treatises of the first order, which were thus brought within reach of all who had at heart the modernising and development of British commercial enterprise. The services rendered by "Griffin's" to the country are clearly indicated by the wide range of industries with which its publications have dealt and continue to deal; the book contains chapters written by specialists who trace the connexion of the house with such vital national activities as shipbuilding, mechanical engineering, mining, metallurgy, textiles, applied chemistry, medicine, hygiene, and sanitation. Medicine and the allied sciences, indeed, have been well represented in the lists of the firm which gave to the world such works as A. W. Blyth's "Manual of Practical Chemistry"; this book was expanded into two volumes—"Foods: their Composition and Analysis," and "Poisons: their Effects and Detection," which are to-day the accepted works of reference in courts of law. R. S. Aitchison's "Medical Handbook" and the "Surgical Handbook" of Caird and Cathcart are examples of the well-known "Pocket" Medical Series of Reference Books. Professor W. Stirling's English edition of Landois's "Textbook of Human Physiology" and the whole "Standard Medical Series" may be mentioned also as having helped to lift the name of Griffin to the high position it now occupies in the publishing world. Lord Moulton, in his foreword to the Centenary Volume, refers to the good fortune which has secured to the firm "in unbroken succession an able and enterprising head." The manner in which its history is here presented and the story itself combine to make clear the loyalty which the business has had at its command, together with the driving force and skilled direction, which have brought to it deserved prosperity.

TEXT-BOOKS ON CHEMISTRY.

Inorganic Chemistry. By JAMES WALKER, LL.D., F.R.S. Eleventh edition, revised and enlarged. London: G. Bell and Sons. 1920. Pp. 327. 5*s.*—We could not wish for a clearer outline of the principles of chemistry than is presented in this unpretentious volume. Dealing with elementary facts it is intelligibly written and, while adapted to the mental grasp of the beginner, prepares the way to a deeper study of the subject. The chapters on ionisation and the rarer elements are excellent, and illustrate the purpose of the author to keep his work up to date. The present issue is the eleventh edition, and will precede many other editions if the standard of modernisation is maintained.

Text-book of Chemistry. By R. A. WITTHAUS, A.M. Seventh revised edition by R. J. E. SCOTT, M.A., B.C.L., M.D. London: John Bale, Sons, and Danielsson. 1920. Pp. 478. 20*s.*—Written admittedly mainly for medical students, it is open to doubt whether this revised edition of a well-known book is not calculated to increase the burden of the medical curriculum. It seems to us that the book is much better adapted to the requirements of the purely chemical student. The relations of chemistry to medicine are practically ignored on the ground that the growth of such relationships is so great as to necessitate separate works on the subject. All the same the bearings might have been indicated, even if only quite briefly.

Intermediate Text-book of Chemistry. By ALEXANDER SMITH. London: G. Bell and Sons. 1920. Pp. 520. 8*s.* 6*d.*—An intermediate study of chemistry is, in our view, an erroneous proposition. Any work written within the confines of the intermediate is bound to overlap extensively both the elementary and the advanced treatment of the subject, and the trouble is indicated in this volume. Many chapters border on industrial questions, which are best dealt with in separate numbers in view of their great technical scope.

Elementary Practical Chemistry. By J. E. MYERS, D.Sc. Vict., and J. B. FIRTH, M.Sc. Vict. Second edition, revised. London: Charles Griffin and Co. 1920. Pp. 194. 4*s.* 6*d.*—This book does not aim at a novel treatment of the subject, amounting as it does to the outlining of a series of exercises at the laboratory bench which are well known. These are, however, well adapted and arranged and in good sequence for the requirements of medical students taking their first examination in practical chemistry. The directions in regard to manipulation form a satisfactory feature of the work.

Qualitative Chemical Analysis. By HENRY W. SCHIMPF, Ph.G., M.D. Third edition, revised. New York: John Wiley and Sons, Inc. London: Chapman and Hall. 1920. Pp. 187. 7*s.*—Primarily intended for students in pharmacy this systematic course of qualitative chemical analysis of inorganic and organic substances outlined in this book will be consulted with advantage by all beginners in the chemical laboratory. The comprehensive tests set out bear witness to the writer's intimate acquaintance with the trustworthy evidence for the presence or absence of the substance sought for, and a demand for a third edition is thus explained. The author is the professor of analytical chemistry in the New York Brooklyn College of Pharmacy.

Applied Chemistry. By C. KENNET H. TINKLER, D.Sc., F.I.C., and HELEN MASTERS, B.Sc. Vol. I. London: Crosby Lockwood and Son. 1920. Pp. 292. 12*s.* 6*d.*—The diploma in household and social science recently instituted by the University of London has brought this book into being. The present volume deals with water analysis, detergents, textile fabrics, bleaching agents, ventilation, fuels, paints, polishes, and so forth. A second volume is promised shortly, dealing with foods. An interesting and attractive feature of the work are the examples of experiments which deal more particularly with problems relating to household matters, not performed in the chemical but in the kitchen laboratory. The subject matter is well and clearly written, but, of course, a knowledge of chemistry is essential to intelligent reading. Students of household science will welcome this publication. It is a practical book, which should prove of general interest apart from academic calls.

Practical Chemistry. By P. A. ELLIS RICHARDS. Third edition. London: Baillière, Tindall, and Cox. 1920. Pp. 149. 5*s.*—This is eminently a book for bench work. The directions are thoroughly practical and manifest the experience of a teacher acquainted with details, careful attention to which leads to successful results. As stated in the preface, all the subject matter in the syllabus of the Conjoint Board preliminary science examination is included, while there are detection tables and volumetric analyses arranged to meet the requirements of the first examination for medical degrees of the London University. A useful section is added on elementary toxicology, and the chapters on preparation of salts are decidedly helpful. The qualitative methods have been brought into line with recent developments.

JOURNALS.

Journal of Pathology and Bacteriology. Vol. XXIII. No. 4. Pp. 371-512. December, 1920.—The Diurnal Variation in the Sizes of Red Blood Cells, by C. Price-Jones.—On the Action of X Rays upon the Transplantation of a Spontaneous Carcinoma of the Rat, by H. Chambers, G. Scott, and S. Russ. A spheroidal-celled carcinoma of the submaxillary gland in a rat failed to grow when inoculated into normal rats, though autologous grafts succeeded well. Transplantations into rats previously treated with rather large doses of X rays succeeded in a proportion of animals, and the tumour subsequently grew fairly well in normal rats.—Hæmolytic Fever, by K. Yamakami. The author believes that the rise of temperature in blackwater fever and other conditions in which hæmolysis occurs in the circulating blood is directly due to the pyrogenetic substances set free by laking the red corpuscles. Experiments on the effect of injecting laked blood and of the lysis of red corpuscles in vivo by the injection of distilled water have given varying and contradictory results. The author shows that it is a question of quantity; small doses of laked blood give no temperature change, moderate doses cause a rise of several degrees, while large doses cause a fall.—Tuberculosis of the Myocardium, by W. W. Adamson.—The Principles underlying Gram's Stain, by T. H. C. Benians. Gram-positive bacteria lose their power of retaining the stain when they are mechanically broken up; the reaction depends therefore on the physical structure of the organism and its cell wall. A variety of experiments lead to the conclusion that the dye forms an absorption compound with the bacterial substance; this is dissociated by iodine, which forms with the dye a large molecular substance which in alcoholic solution will not readily pass through the cell wall. Some Gram-negative organisms combine with the stain, but have a membrane which lets the dye-iodine compound through (e.g., gonococcus), in others there is no real permeation by the stain (e.g., coli).—The Splenic Lesions in Splenic Anæmia, by E. H. Kettle. In five cases of splenic anæmia the spleen, removed by operation, showed at least four distinct lesions: one was Gaucher's disease, one possibly tuberculosis, two probably "Banti's disease," and one quite indeterminate. "Splenic anæmia" is evidently not a homogeneous disease. Good illustrations accompany this paper.—The Effect of Osmic Acid and other Agents on the Affinity of Receptors for Immune Bodies and on their Antigenic Properties, by M. Kosakai. Stromata of red cells treated with osmic acid absorb immune body unspecifically, but act as specific antigens.—A New Apparatus for Accurate Blood-Gas Analysis, by J. S. Haldane. A combination of the author's apparatus for oxygen-capacity determinations by ferricyanide, with the compensatory arrangement of his gas-analysis apparatus by which determinations of O_2 and CO_2 in blood, &c., can be conveniently and accurately achieved.—Observations on the Gases in Human Arterial and Venous Blood, by J. Meakins. Using Hürter's method of obtaining samples of blood by direct puncture of the radial artery with a fine needle, the author shows that on the average arterial blood is 95 per cent. saturated with oxygen; breathing air enriched with oxygen raises this to 99 per cent., while 10 minutes' respiration of air containing only 12 per cent. oxygen reduced the saturation to 81. Holding the breath for 40 seconds reduces the saturation to 84 per cent., and substantial reductions are also caused by the rapid shallow breathing which is characteristic of pneumonia and some nervous states.—Experimental Study of Gastrotoxic Serum, by Y. Miyagawa. Following out Bolton's work on gastrolytic sera, the author demonstrates the production of isogastrolysin in a proportion of animals. Rabbit *v.* guinea-pig and rabbit *v.* rabbit immune sera will both act on rabbits' and guinea-pigs' stomachs. There is no specificity between the fundus and pyloric areas.—The Effects of X Rays on Lymphocytes, by S. Russ, H. Chambers, and G. Scott. Brief exposure to X rays reduces the lymphocytes in rats' blood by some 50 per cent. after about one hour, after which there is a gradual return to the normal; further doses of rays now produce no effect.—The Pigments of the Adrenals, by G. M. Findlay. The lipochrome pigments consist of carotin and xanthophyll, and possibly a third substance; melanin is of endogenous nuclear origin. All are increased in conditions of cell depression.—The Leucocyte Changes in Pellagra and Beri-beri, by G. M. Findlay. In pellagra neutrophils are normal, lymphocytes increased; in beri-beri both are decreased.—Palatal Tumour with Structure of Mixed Parotid Tumour, by J. Ritchie.—Obituary Notice, with portrait of the late Professor A. R. Ferguson, of Cairo.

New Inventions.

INSTRUMENTS FOR THE RELIEF OF DEAFNESS.

WE have examined various instruments for the relief of deafness designed by Mr. W. H. Pettifor, telephone engineer, 11, Victoria-street, London, S.W., and shown at the London Medical Exhibition last October. Two of them are of a novel character.

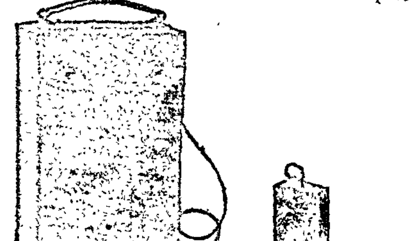

FIG. 1.—Bone Conduction Instrument.

Bone Conduction Instrument (Fig. 1).—This instrument has been designed for cases of obstructional deafness, where conduction of sound through the bone may be necessary. By lightly pressing the knob against the teeth or any part of the skull (directly behind the ear is an excellent place), vibrations are conveyed to the auditory nerves in much the same way as sound to the normal ear. The whole set comprises a transmitter, which contains a highly sensitive aperiodic microphone, a pocket battery, and the usual receiver. For purposes of practical use this instrument appears to be still in an experimental stage, but it may prove useful in a limited class of deafnesses.

Laryngeal Transmitter (Fig. 2).—This instrument consists of a transmitter which is placed against the larynx and held there by means of an adjustable band. This transmitter gives a very good wave-form on account of cutting out the transmitter diaphragm, thus excluding all extraneous sounds. The transmitter is connected to a small dry battery and a receiver, the latter being adjusted to give the most suitable pitch and strength. This instrument should be useful in teaching lip-reading, as the lips of the teacher are not obstructed by an instrument being held in front of them, the pupil also hearing the sound of the words. Another use to which this instrument could be put with great advantage is reading to a deaf person for a long period, as it is unnecessary to hold the transmitter, and the reader's lips can be observed. From personal trial we think this instrument likely to be of value in high degrees of middle-ear deafness.

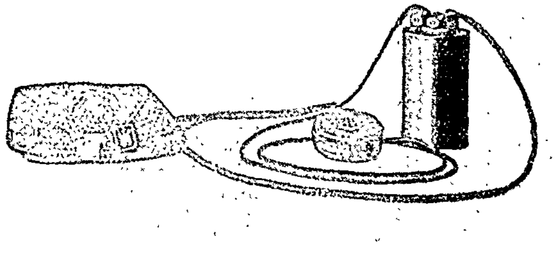

FIG. 2.—Laryngeal Transmitter.

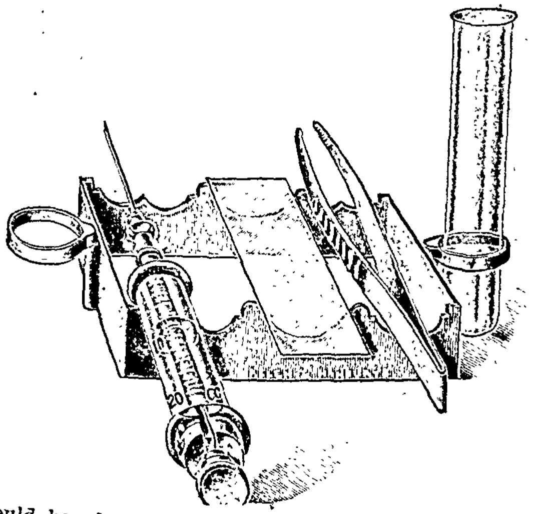
A SIMPLE TRAY.

FINDING the need of a simple rest or tray for the impedimenta which are used in giving tuberculin injections, I have designed the tray shown in the accompanying illustration. The requisites for such an appliance are simplicity, stability, and asepticity; the tray will be found to meet these requirements. Dr. H. A. Ellis (Hackney Infirmary) has suggested to me that it would be of more value to laboratory workers if the spaces were adapted to hold slides and if a holder for test-tubes were added, and these alterations have been made.



The tray has been made for me by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W., who have constructed it to my design.

Gordon-square, London, W.C.

F. E. GUNTER.

THE LANCET.

LONDON: SATURDAY, JANUARY 1, 1921.

The New Year.

The beginning of the year is used by all thinking people, by all people that is who revise the plans of the future by the experience of the past, as a season in which it is convenient to take stock of their position; and what holds good for thinking individuals should hold good for a learned profession. But such provisions and revisions, to have full value, should not be too limited, for, as has been frequently pointed out, any tendency to regard the separate years as defined periods rather than as arbitrary subdivisions of time may lead either to unwarranted optimism or to feelings of depression which fuller consideration would not confirm. The prospect of medicine for the new year is both wide and perplexing. On the one hand, many new avenues of medical progress, and even of medical adventure, have been opened up, and large schemes, for the most part founded upon large ideas, have been laid before us; but, on the other hand, the means to traverse these avenues and the opportunities for carrying out these schemes seem, for the moment at least, to have been withdrawn. There is no money. With the roll of unemployment as it is, and with the vast demands on the country necessitated by an unprecedented war, there can be little prospect of money in large sums being forthcoming immediately for purposes of medical administration. It is clear that only the most urgent demands are likely to be satisfied, and the probability is that the satisfaction given will be but partial. And if the State is thus hampered, private individuals are no less so—disregarding prices and disregarding money values, we have only to look, as most of us are doing or have recently done, at the income-tax demands to realise how difficult it will be in the immediate future to rely in any large extent upon personal generosity. That is the pessimistic side, which we suggest may often seem less black when its shadows are steadily scrutinized.

The failure of Parliament at this juncture to attend with sympathy to the requisitions of the Ministry of Health in matters of grave national urgency is largely accounted for by the fact that the public have not appreciated the measure of that urgency; following an easy lead given to them in many places, they have fallen into the belief that the Ministry of Health, in its hurry, is willing to embark on a course of unconsidered expenditure. We believe, as well as hope, that such a view will not long prevail. It may be in the minds of our readers that much the same mental attitude was popular, and was superficially justified, upon the introduction of the National Insurance Act, but quite soon legislation for national insurance against sickness and its results was seen to be one phase in a consecutive story, the story of the development of medical practice; and though many deplored, and may still deplore, the machinery inflicted upon that development—going even so far as to speak of it as retrogression—we must own that the Insurance Act followed upon a wider understanding by the public of the essential part that medicine must play in social reform. And that is the position which to-day is more obvious than it was seven years ago. The public demand from medicine to-day, from every branch, section, and division of our calling, that we should assist in the improvement of the social, moral, and physical conditions of the State. The influential valuation of medicine is shown by the fact that day by day a medical side of things makes itself apparent, compelling from intelligent people the recognition of the spread of our science. This being so, it is perfectly impossible to believe that the difficulties with which we now struggle will remain permanent through lack of money. But while money is not forthcoming the work of medicine must not be allowed to stand still. Let us remember that if less money is available for carrying through large schemes there is less need for money in many directions, inasmuch as in the last few years a levelling down of riches has been accompanied by a levelling up of poverty. The improvement of nutrition in the London school children, and even in the condition of their teeth, which is perhaps the best criterion of early nutrition, points this out clearly enough. The effect of this levelling on the financial aspect of general practice has not yet been fully realised, but experience has somewhat unexpectedly shown a growing content with the remuneration derived from contract practice on present lines. And it would require a national cataclysm to upset the capitation basis of the large part of medical practice for the next generation.

Another consoling reflection is the increasing willingness of all ranks of society to respond to the teaching of hygiene. Grandmotherly legislation and fatherly local authorities were doubtless necessary to start, let us say, the mining community on the paths of true health; but having seen a little of what medical skill and hygienic protection may do for his happiness and efficiency, the miner, at all events, is taking his medicine seriously and is inclined to make the arrangements for himself. It seems to us that the future, if we look at it without passion or prejudice, is by no means discouraging as regards medicine in its broader aspects of national health and efficiency.

Insanity and Responsibility.

At a recent trial at the Central Criminal Court, Albert John Bartlett, indicted for the murder of a woman, was found by the jury to have been guilty of the act, but to have been at the time insane and not responsible for his actions. The trial has given prominence again to the questions arising out of the rule laid down in connexion with McNaughten's case in 1843, and since followed of necessity in all such cases; this makes the crucial question in determining legal responsibility, whether the accused understood the nature and quality of his act and knew that it was wrong. Sir Robert Armstrong-Jones, who was called for the defence by Bartlett's counsel, had examined the prisoner in Brixton Prison, and gave evidence as to conditions he had observed. In the course of cross-examination and of questions put to him by the judge, he expressed the view that the rule laid down in McNaughten's case in the early half of the last century was antiquated and required revision in the light of more recent medical knowledge than was then available. Mr. Justice DARLING, in summing up to the jury, called their attention to evidence upon which, in accordance with the existing law, they might find that the accused was insane, and this they did as stated above. His lordship, however, in the course of doing this, commented upon the views of Sir ROBERT ARMSTRONG-JONES as to the accepted rule in such cases, and is reported as having said: "We take the law of England from the King's Bench, and not from Harley-street; from the House of Lords, and not from Wimpole-street or any other street." As to this, it is hardly necessary to point out that a medical witness, like any other witness, is obliged to answer truthfully questions put to him in cross-examination or by a judge. If he holds an opinion as to a rule of law, and is asked what it is, his reply can hardly be treated in fairness as an attempt on his part to dictate to the court. Apart from this, the learned judge's remark has given publicity to a question upon which many medical men hold strong opinions.

This they have as good a right to do as members of the legal profession, and their other fellow citizens, the question being not what the rule of law is but whether it falls short of being what it ought to be. The point raised may be stated, perhaps, thus: a man may be insane, even to the extent of being recognised and certified as such, so that he is detained in an asylum, and may yet be capable of knowing the nature and quality of the act of killing another, and of knowing that it is wrong. He may, however, some day commit that act, still knowing its nature and quality, and still knowing that it is wrong, but impelled thereto by insane impulse, through a defect of will-power, such impulse being irresistible, dominating, and compulsive. Sir HERBERT STEPHEN, writing from long and wide experience of criminal trials, has, inter alia, replied to this view, as stated in the *Times* by Sir ROBERT ARMSTRONG-JONES, holding that there is no need for a jury to have the question put to them, "Could he help doing it?" because, in fact and in practice, when they think that a man has acted under an insane and irresistible impulse, they always answer in the negative the question now put to them: "Did he know what he was doing and did he know it was wrong?" Such an argument will not convince those alienists who find the present law to need revision. Their view will probably be that the fact that juries find verdicts, frequently or generally, which could be shown not to be in accordance with the law, if their reasons for arriving at them could be analysed, is no reason why the law should be left without change or challenge. Their conclusion will rather be that such a condition of things points to the desirability of inquiry, in order to ascertain whether the rule should not be altered, so that it may commend itself to juries and be universally and lawfully followed.

After all, the principle to be kept in view can hardly be denied. The law permits a special verdict to be returned in the case of certain prisoners because, owing to their proved mental condition, to punish them as ordinary criminals would be contrary to justice and humanity. It is asked now whether a standard regarding the mental condition to be proved which was set up three-quarters of a century ago accurately interprets modern conceptions of what is just and humane. It seems to us quite likely that it is nothing of the sort, and at all events the serious question remains for investigation as to what weight should be given to medical as well as to legal opinion.

◆

Occupational Hygiene and the School Medical Service.

THE annual report of the chief medical officer of the Board of Education concludes with the sentence:—

> The final product of the School Medical Service should not be a statistical record, but an alert and growing individual, equipped for the manifold functions of life, able to work with efficiency, able to enjoy life with keenness and appreciation, a healthy member of a healthy community.

Various suggestions are forthcoming as to why achievement lags so far behind intention. One is given in the current number of *School Hygiene*, a journal which has kept interest alive in the scientific aspects of school health and has had an influence outside its immediate circle. We are glad, therefore, to learn that the journal is to enjoy a renewed existence under the editorial guidance of Dr. JAMES KERR and Dr. C. W. HUTT. A valedictory article, written under the shadow of discontinuance, takes a serious view of the outlook for school hygiene as a branch of scientific knowledge, suggesting, in fact, that progress in this direction during the last decade has been almost negligible. A point is made of the crystallisation of procedure into forms and schedules, which, it is allowed, favours the accomplishment of routine, but which, at the same time has its drawbacks. These are summarised as follows:—

> "The technical work of school hygiene has been discounted by shibboleths which have placed the responsibility on medical officers of health, so that the people who know and do the work do not get the credit or hearing which they deserve. Unconsciously interest and pride in their work suffers, and now the whole status of the service has been so lowered that it may be regarded as a blind alley into which the young practitioner should only venture with the utmost circumspection. Yet school hygiene, if the methods of science were properly regarded, is of prime importance, and has a rich harvest to yield. It should even now be giving much greater value for the money spent, often, indeed, in largely wasted efforts."

Fortunately the article does not stop at this harsh indictment, which fails to recognise the difficulties of administration, but proceeds to suggest the remedy—namely, that the whole field of hygiene in schools should be opened up for educational research and treatment, the Universities to recognise training in this fundamental branch of occupational hygiene and to institute a diploma in it. The proposed training would have as its basis the proper handling of statistics in investigations of distribution and association, a broad knowledge of physical conditions—heating, lighting, ventilation, and the like—and of the problems of social disease and healthy living in general. Study of fatigue symptoms and their indications, the physiological effects of food, rest, and recreation would constitute a first part of the course, to count as the equivalent of the public health diploma course. The second part would comprise a knowledge of industrial conditions and of school hygiene, on which the industrial efficiency of the human unit primarily depends. The occupational environment of the growing child, or, in other words, educational hygiene, is still in a plastic condition, and its study would be comprehensive under this intensive attention, and include, among other things, a consideration of bodily and mental development and retardation, and the effects of artificial conditions on the growing organism.

For ourselves, we are satisfied that the position of medical officer to an Education Committee, especially if he also advises the Committee for the Care of the Mentally Defective, is one full of scientific interest. He will have, in fact, barely time to make use of all the material which passes through his hands. But the position of the assistant school medical officer, if limited to inspecting children and filling up Board of Education schedules, must obviously be monotonous. Some senior officers see to it that their juniors have clinic work as well, but the medical profession as a whole has set its face against the school medical officer undertaking any treatment except affections of the skin and minor ailments. To carry out the Education Act of 1918 will involve the employment of many more assistant medical officers, so that the individual prospect of becoming a senior in the service will become more remote. The suggestion, therefore, that the School Medical Service should be widened to include duties with regard to factories and employees is welcome, and would give more scope for research. The school doctor knows all about the young people, and is in a better position to carry out the work than the certifying factory surgeon. To sum up: Add to the school medical officer's work the supervision of young people and the care of the mentally defective, plan out a special course of study for industrial and school hygiene, provide a stimulus to research and inquiry, and in a comparatively short time the School Medical Service would not only be content, but would attract from abroad seekers after that knowledge which it is in its power to gain and to give. But the abuses to which a multiplication of special diplomas may lead are, we presume, well known to the School Medical Service, and the conditions for obtaining the projected diploma will have to be carefully thought out.

The Financial Position of the Hospitals.

A CONFERENCE of Representatives of the Honorary Staffs of Voluntary Hospitals was summoned just before Christmas by the British Medical Association. The gathering was presided over by Sir JAMES GALLOWAY in the Barnes Hall of the Royal Society of Medicine, and we give in another column a brief account of the discussion, as well as the interesting conclusions that were arrived at. At the outset of the proceedings a resolution was passed recording the view of the meeting that the voluntary method of administration is to the advantage of the public, of medical science, and the medical profession. And while various other resolutions expressed approval of State subsidies, the necessity for greater help from employers of labour, and the value of patients' contributions, one speaker, Dr. ASTLEY CLARKE, describing the position of the Leicester Royal Infirmary, was able to tell the meeting that at this institution solvency had always been maintained under the voluntary system, through the intelligent regard by the administration of the particular qualities and needs of the centre and district. Two other important points emerged from the discussion—rather from the views expressed than from the words of any resolution. First the meeting concluded that payment by the State for pensioners, or by the National Insurance Commissioners for panel patients, in no way detracted from the voluntary status of an institution. And, secondly, that it is right that the honorary staffs of voluntary hospitals should receive payment in certain circumstances, but, of course, when the claims of the hospitals for maintenance have been satisfied. The Conference is to be the prelude of similar gatherings, it being clear that it would be advisable to consider in this reasoned way many other important matters in connexion with the financial position of the hospitals. In this connexion we may refer to an important communication published this week from Dr. J. C. MUIR, medical superintendent of the Whipps Cross Hospital of the West Ham Board of Guardians. Dr. MUIR is writing in reference to the recent discussion at the Harveian Society upon the future of the Poor-law infirmaries—a discussion which will be renewed at the end of this month; but what he says has its distinct message to all who are concerned with the voluntary hospitals, for these must be affected by the elevation of the Poor-law infirmaries to general hospital rank. The question, for example, of the payment of medical staffs will enter a new phase when any practical linking-up occurs between the voluntary and the Poor-law hospitals.

A PRIZE IN OPHTHALMOLOGY.

Mr. W. EDMONDS and Miss S. EDMONDS, of Wiscombe Park, Colyton, have founded a prize in ophthalmology in memory of their brother, NICHOLAS GIFFORD EDMONDS, Lieutenant, 2nd Black Watch, who fell at Magersfontein on Dec. 11th, 1899. The prize is £100, and is awarded every two years for the best essay on a subject dealing with ophthalmology and involving original work. The competition is open to all British subjects holding the medical qualification. Subject to certain legal regulations, the management of the prize will be in the hands of a committee nominated biennially by the Medical Board of the Royal London Ophthalmic Hospital, who will select the subject of the essay and elect two examiners. The winner of the prize will have the option of giving a lecture on the subject at the Royal London Ophthalmic Hospital. The Middlemore prize, awarded triennially and run on very similar lines, has rendered valuable service to ophthalmology, and many of the prize essays remain as standard works. It may certainly be expected that this generous gift awarded biennially will also act as a strong stimulus to original work. There cannot be too many such incentives to break away from routine in professional life, and to stimulate initiative; many men have originality and power of investigation, but from lack of stimulus do not settle down to any definite line of research. The setting of a concrete subject is often all that is required to fire a man to carry out a valuable piece of work. By indicating the subject of the essay two years before the award ample time is afforded for thorough observation, carrying out experiments, and careful compilation. Mr. and Miss EDMONDS have placed the medical profession under a deep obligation by their intelligent liberality. Their wish in founding the prize is that suffering may be alleviated, and it may be confidently anticipated that this end will be attained.

Annotations.

"Ne quid nimis."

IN MEMORY OF HUXLEY.

Huxley once said that the only instruction of educative value that he had ever received was that given in the lectures on physiology delivered by Wharton Jones at Charing Cross Hospital Medical School. It is therefore peculiarly fitting for the lecture founded at Charing Cross Medical School in Huxley's memory to be delivered by a physiologist. Of the 11 lectures held since his death in 1895, three have now emanated from the heads of physiological laboratories. In 1896 Sir Michael Foster inaugurated the lectureship with a discussion of the influence on subsequent medical thought and procedure of three physiological discoveries made at about the time that Huxley was a student—the work of the brothers Weber on the inhibitory action of the vagus, the experiments of Bernard leading to the conception of the vaso-motor system, and the researches of Waller on nerve degeneration. In 1906 Professor J. P. Pavlov gave an account of his experimental investigations into the psychical faculties of the higher animals; and this year Professor Gowland Hopkins, no less illustrious than his physiological predecessors, has given the important exposition of the present ideas on nutrition which we publish on p. 1. In a few remarks introductory to his lecture Professor Hopkins spoke of the responsibility felt by him on this occasion, which was the greater inasmuch as the lectures had suffered interruption through the catastrophe which had made a breach in the continuity of most things. He pointed out that the passage of these tragic years seemed to have given a disproportionate remoteness to the life and times of Huxley: for it was now no more than a quarter of a century since Huxley died, and barely 40 years since the days of his main activities. Professor Hopkins said that to many, if not to most, of his predecessors in the lectureship, Huxley was personally known, but that he himself had no memories due to such acquaintanceship, and it was to be feared that they would not belong to many of those who would follow him. These lectures indeed were fated soon to lose a particular character which had hitherto been attached to them. A very few more years and the thoughts of the audiences would be directed towards a figure wholly historic, even as elsewhere they were directed on similar occasions to the personalities of the older heroes of medicine and of science. But yet for mid-Victorian science Huxley's gifts provided both sword and buckler. It is not too much to say that in those days the younger biologists, while profiting from his scientific labours, worked with a definite sense of his protection. Professor Hopkins voiced the regret of us all that in his peculiar position as the champion of scientific aims Huxley has had no true successor. His pen would have seen to it that the services of science to the nation during the war should not fade from the public memory as they are fading to-day. We miss the gifts we commemorate.

CHRONIC GASTRIC DISORDERS.

SPEAKING from an experience of nearly 30 years and almost a thousand hospital gastric cases, Mr. A. E. Maylard, in the first of three interesting James Watson lectures delivered last year in Glasgow, and now published in booklet form, deals with chronic gastric disorders dependent upon other causes than those of an ulcerative, carcinomatous, or obstructive nature; and he points out that, owing to the great successes of gastric surgery during the last 25 years, a large number of patients come under the care of the surgeon for gastric symptoms which are not due to organic disease of the stomach or duodenum. Therefore, he draws attention to the care required in diagnosis and the need for collaboration between physician and surgeon, so that operations should not be undertaken for gastric symptoms due to organic or functional disease of the nervous system, such as locomotor ataxy, hysteria, neurasthenia, or to such distant sources of infection as dental caries and diseases of the nasal sinuses. He speaks of three primary essentials to be cleared up in every case:—

> "(1) Whether it is the stomach itself that is the cause of the symptoms; (2) whether it has become the seat of functional or organic derangement as the result of mischief elsewhere; or (3) whether the symptoms are merely apparently connected with the viscus; that is to say, the stomach is quite healthy in itself, but the symptoms which appear to be gastric are merely the referred indications of disease in some other part of the body."

The need is also pointed out for regarding an operation for gastric symptoms as an exploration of the whole abdomen, so that causes of reflex gastric symptoms, such as cholecystitis, chronic pancreatitis, and diseases of the intestines, appendix, and female genital organs, may not be overlooked. Mr. Maylard considers that the frequency and importance of appendical dyspepsia has been greatly exaggerated. In many cases an exploration is still necessary to settle the diagnosis, so that organic disease, such as chronic ulcer and carcinoma, may be found and treated in its early and hopeful stages.

For the treatment of chronic gastric ulcer Mr. Maylard leans to partial gastrectomy, disregarding the teaching of long experience that gastro-jejunostomy, with or without excision or cauterisation of the ulcer, cures the large majority of these patients with a much smaller risk. For diagnosis he relies chiefly on the clinical symptoms and expert radiographic examination. He does not believe much in "test-meals," but apparently has no experience of repeated examinations at short intervals after a meal—a method which, when well established, may make us all change our views. For duodenal ulcer he recommends that "if the part of the duodenum implicated cannot be freely mobilised so that the involved bowel can be excised, gastro-jejunostomy must alone suffice," but excision of the ulcer-bearing area appears to us unnecessarily severe, especially when such a comparatively safe and simple operation as gastro-jejunostomy cures over 90 per cent. When there has been serious hæmorrhage Mr. Maylard recommends, in addition, exclusion of the duodenum by "completely severing the stomach at its pyloric extremity," because he believes that bleeding is less likely to recur when the food cannot pass over the ulcer and the peristaltic wave may be interrupted.

With regard to gastric carcinoma he quotes Dr. C. H. Mayo:—

> "The most common cancer is that of the stomach. More than one-third of the cancer in men, and more than one-fifth of the cancer in women appear in this organ; and, inasmuch as the condition in nearly one-half of such patients who come to the physician for examination is inoperable, there is room for some improvement in the matter of securing earlier recognition of the disease" (*Annals of Surgery*, 1919, p. 236).

He also advocates that steps should be taken to educate the public upon this subject, so that patients should seek treatment while the disease is in its early stages. Mr. Maylard divides the causes of pyloric obstruction into anatomical and pathological, the latter depending on new growths. As regards the former, he pointed out in 1904 that, quite apart from congenital hypertrophic stenosis of the pylorus, a developmental narrowing of the orifice existed in some cases, and very gradually gave rise to obstructive symptoms. He has himself operated on 36 patients suffering from this condition with satisfactory results. Landerer had previously and independently drawn attention to the same condition, which is due to an excess of reduplication of the pyloric fold whereby the width of the valve is increased and the channel diminished, so that it will not admit the index finger. As a result of this partial obstruction the stomach hypertrophies and ultimately dilates when the muscular power gradually diminishes. For this condition Mr. Maylard prefers gastro-jejunostomy to Finney's operation, and he advocates gastro-jejunostomy also for ordinary pyloric obstruction following ulceration; in this case he makes his anastomosis as near the pylorus as possible. Mr. Maylard does good service by again drawing attention to the variable and often misleading symptoms and radiographic appearances of partial pyloric obstruction, the symptoms and signs often disappearing when the patient is at rest under good conditions, only to reappear when he returns to work. Mr. Maylard strongly advises operation when the symptoms of undoubted gastric disease do not completely recover after a reasonable period of conservative treatment, in order to avoid the serious consequences of delay in cases of ulcer, carcinoma, or obstruction.

SILICOSIS ON THE RAND.

THE main interest of the report just published[1] of the South African Miners' Phthisis Board for the year ending July 31st, 1919, lies in the portion contributed by Dr. W. Watkins-Pitchford, chairman of the Medical Bureau. The importance of the work which is being conducted on the Rand in relation to silicosis may be appreciated from the statement that 4000 persons were, during the year, submitted to the careful examination required before men are permitted to commence work underground, while some 15,000 men are being kept under regular observation at periodical examinations. Indeed the activities of the Board probably represent the most complete and intensive inquiry ever made into the occurrence of any disease, and their annual reports must gather in interest as time goes by. Unfortunately for medical science, the period now reported upon was interfered with by the enlistment and subsequent return to the goldfields of many miners. Nevertheless, even this interruption in the normal course of employment has been utilised to throw light on the occurrence of the disease. Thus, in some instances,

> "miners of many years' standing, who had but slight apparent damage to the lungs on leaving, showed definite physical signs upon their return from military service; and in more than one instance a miner of long service, who left with apparently a normal chest, returned in a condition of fully developed primary silicosis."

Development of silicosis in the absence of exposure to risk had previously been suspected, now it is a proven fact. A further important point must now also be accepted, namely, that—

> "Tuberculous infection will often bring about a rapid development of silicotic changes in the lungs of a miner who has habitually inhaled siliceous dust but who may have hitherto shown little or no indication of pulmonary damage. ...... In these cases one might almost say that the *tuberculosis has 'predisposed' to the silicosis;* such a statement is, indeed, true in its literal sense with respect to men who are the subjects of tuberculosis before they begin hard-rock mining."

The statistics quoted do not yet indicate any beneficial results from the recent improved conditions of underground work. This is due partly to war-time interference with employment which has rendered comparison with figures of former years impossible, and partly to the fact that results are not yet due in a disease with so slow an onset. "We have, meanwhile, to gather the residue of the evil crop which sprang from the ignorance and indifference of the past." The value of initial examination, which commenced September, 1916, and has been applied to 5175 men (of whom 2741 are known to be in underground employment), is clearly shown by the fact that only one has developed tuberculosis and no one silicosis. If this remarkable record is maintained the disease will be swiftly eradicated from the mines. Meanwhile although the toll it is taking of those at work before 1916 remains high—viz., 55 cases of silicosis or of silicosis with tuberculosis per 1000 working miners—"of a total of 3166 men who had worked, on the average, for a period of nine years and six months, only 349, *not all*, had become silicotic; the proportion was only 1 in every 9, or 11 per cent."; while of these silicotic cases only 15·6 per cent. were affected with tuberculosis—the complication without which silicosis would be a comparatively innocuous pathological condition. We await further reports, which must be of great moment to all those concerned with the administration of schemes under our own Workmen's Compensation (Silicosis) Act of 1918.

EFFECTIVE X RAY THERAPEUTICS.

AT the December meeting of the Section of Electro-therapeutics of the Royal Society of Medicine (p. 24) a description was given by Dr. Reginald Morton of a system of treatment, primarily aimed at the cure of uterine carcinoma, that may have a profound influence upon radiological and surgical procedure in the treatment of malignant disease in general. Dr. Morton spent a week in the Women's Clinic at Erlangen studying the methods there employed, and he came away with the conviction that the apparatus and technique constitute a real advance in radiology. No new principle is involved, but special tubes have been designed to give a greater degree of penetration and intensity than has hitherto been available. Until now the loss of radiation by dispersion and absorption has been sufficient almost to nullify any effort to destroy deeply seated malignant growth. With the system here described, for which Privat-dozent Dr. Hermann Wintz (who succeeds Dr. L. Seitz as professor at the end of the present session) is mainly responsible, nearly 20 per cent. of the skin dose is transmitted to a depth of 10 cm.; hence by using simultaneously a number of portals of entry for the rays the treatment of central carcinoma becomes practicable, for it has been found that a cancerous growth will disappear if its whole mass has been subjected to a dose only slightly in excess of that which normal skin will stand without serious injury. Over 80 per cent. of cases of uterine carcinoma, with more or less involvement of the parametria, treated by this method alone during the year 1918, are still well and leading normal lives. It is the same with 75 per cent. of cases of mammary carcinoma treated without operation during 1917. The method is, of course, inapplicable after general dissemination has occurred, but it is not too much to hope that most cases of malignant disease will come under skilled observation before this serious condition arrives.

Another class of disease that has given excellent results with this method of treatment is the tuberculous gland and joint, especially in young subjects where the disease has not progressed to actual destruction. A notable feature of the system is the high degree of accuracy in the dosage. Nothing is haphazard; every dose is a separate calculation, and the whole procedure is standardised so far as the present state of knowledge permits. We are gratified to learn that similar equipment is being installed in at least two London hospitals, so that the advantages of these discoveries will soon be available for all. The results will be watched with keen interest.

GONOCOCCAL ENDOCARDITIS IN A CHILD.

SINCE Thayer and his associates at the Johns Hopkins Hospital established the specific nature of the endocarditis occurring in gonorrhœa many cases have been studied in adults, but the complication in the gonorrhœal vaginitis of children is rare. In the *Journal of the American Medical Association* of Dec. 11th Dr. H. L. Dwyer has reported the case of a girl, aged 23 months, who was admitted to hospital with painful swelling of the left ankle and wrist.

> The illness began three weeks before with pain, swelling in left foot, fever, and vaginal discharge. A friend living with the family also had a vaginal discharge. The child was poorly nourished and irritable. Moving the limbs caused great pain. The skin was yellow and the sclerotics were of a greenish-yellow tint suggesting jaundice. The left ankle and wrist were swollen and very painful. In the lumbosacral region was a superficial abscess 2 inches in diameter. A vaginal discharge was present. The apex beat was just inside the nipple line in the fourth interspace. The heart was beating rapidly and irregularly. A soft blowing systolic murmur was audible over the entire cardiac area, was heard best at the apex, and was transmitted to the axilla. The abdomen was distended. The temperature was 104°,

---

[1] Annual Report of Miners' Phthisis Board, Union of South Africa. Capetown, 1920. 6s.

pulse 140, and respirations 42. Smears from the discharge showed many Gram-negative intracellular diplococci. The abscess was opened, and similar organisms were found in the pus. A culture from the blood also showed them. Under rest the pains in the joints subsided, as did the abdominal distension. The spleen could then be felt to extend 2 inches below the ribs. The cardiac murmur became harsh and intensified, and death took place on the seventh day in hospital. The necropsy showed greenish-yellow cauliflower vegetations on the free borders of the mitral valve. Cover-glass preparations from the valve revealed Gram-negative diplococci.

Gonococcal endocarditis in children is rare. Satterthwaite in 100 cases of endocarditis in New York children found only one due to the gonococcus. Abscess in the subcutaneous tissue or in muscle has been observed in a few cases of gonorrhœa. Dr. Dwyer suggests that the abscess in the sacral region in his case was the result of localisation of organisms from the blood stream due to lowered resistance in that area from pressure. The usual features of gonococcal endocarditis are irregular intermittent fever, chills, and anæmia, and do not differ from those observed in endocarditis due to other organisms. An increase in the intensity of the murmur from day to day, such as was found in the present case, has been noted by several observers.

THE EAR AS PROTOTYPE OF THE TORPEDO.

Dr. H. Hartridge, in the *Journal of Physiology* (vol. liv., No. 4), offers an ingenious suggestion to account for the well-known association in the inner ear of such diverse and differently constituted apparatus as the semicircular canals, the otolith mechanisms on the one hand, and the cochlea with its adjuvant fenestræ, fluids, and middle-ear chain of ossicles on the other. The suggestion is that the mammalian organ subserved in the ancestors of mammals the function of perceiving depth below water surface, and was therefore associated with the semicircular canals and otolith organs in the identification of position and direction of travel. As the author shows, there is a close mechanical analogy between the auditory apparatus of mammals and the depth-controlling gear of the naval torpedo. In the latter are two mechanisms which operate together to control the depth at which the projectile shall travel beneath the surface of the water. 1. A pendulum under the influence of gravity records any deflection that the long axis of the torpedo may make with the horizontal, and if such deflection exists it turns the horizontal rudders in such a direction that the deflection tends to be corrected. 2. A hydrostatic membrane, a sheet-rubber diaphragm, situated in the side of the torpedo in contact with the water outside and on the inside with the air-filled interior. As the torpedo gets deeper in the water the hydrostatic pressure tends to press the diaphragm inwards against a resisting spring. If the torpedo is at the correct depth at which it is required to travel, the hydrostatic pressure produces a force on the diaphragm that is just balanced by the force exerted in the opposite direction by the spring; but if the torpedo gets too deep or too shallow the forces no longer balance, and the diaphragm is pressed inwards or allowed to move outwards respectively, and this causes appropriate deflection of the rudders. If pendulum and hydrostatic membrane operate together, it is found by experiment that the one eliminates the tendency to deflection caused by the other, and the torpedo is thus caused to travel along a straight path at a given distance under the surface. Applying these results to the fish, the latter for the proper direction of its path in three dimensions in space would requre at least a mechanism to give information concerning depth below surface and one to be influenced by gravity, and therefore to show deflection from the horizontal axis. The latter mechanism is identified as the otolith organ. Dr. Hartridge suggests that the tympanum, middle ear, and cochlea are to be identified as the depth-recording mechanisms, the tympanum being the counterpart of the rubber hydrostatic membrane of the torpedo, the ear ossicles the counterpart of the levers which transmit the motion of the diaphragm under varying hydrostatic pressure to the rudder-control mechanism, the stapedius muscle acting as the spring which in the torpedo balances the forces produced in the diaphragm by the hydrostatic pressure. Any mechanism for recording changes in hydrostatic pressure has a fluid—e.g., water on one side of the diaphragm, and a readily compressible fluid, gas, or air on the other side, with arrangements for renewing the air, as it is liable to be absorbed. In shallow water fish and in most reptilia the renewal of air in the middle ear is readily affected by the fish coming to the surface of the water and taking in the air and equalising the tension by the mouth and Eustachian tubes. In some fish the air in the swim bladder is renewed in a similar way. In certain fish living below the surface there is a special connexion with the gas-secreting gland, the swim bladder. In many osseous fishes this is effected through a connexion between the swim bladder and the middle ear by means of a tube, or the swim bladder itself forms the chamber, the change in volume of which (with change of depth below surface) brings about movements in the mechanism which connects with the middle ear, as in carp, loche, and sleat-fish. The remarkable mechanism of articulated bones which connects the ear and the swim bladder in the Siluridæ seems to be associated with the perception of depth and not with audition—and is for measuring air-bladder volume under changes of hydrostatic pressure. The view is advanced that the auditory apparatus of mammalia, which is represented by the cochlea, fenestræ, ossicles, and tympanum, once formed in their ancestors an apparatus for perceiving not sound vibrations but the depths below sea-level. Granting this, it would explain why the cochlea, semicircular canals, and the otolith organs are associated together anatomically, and have a common nerve; and if the cochlea perceives depth below surface all three will be directly concerned with the perception of position and the control of direction.

INDIGENOUS MALIGNANT TERTIAN MALARIA.

A CASE of malignant tertian malaria contracted by a resident of Liverpool and ending fatally was reported by Professor E. E. Glynn and Dr. J. C. Matthews at a recent meeting of the Liverpool Medical Institution. The case is of unusual importance on more than one ground. Not only is it the first recorded instance of indigenous malignant tertian malaria occurring in England since our knowledge of the differentiation of the various forms of malaria has attained its present high degree of precision, but the disease was contracted in a district considerably to the north of the areas where indigenous malaria has in past times been prevalent. Further, the case stands alone as the only reported instance of fatal indigenous malaria of recent years. The patient was a girl, aged 18; she was a native of Liverpool, and had lived in the same house in the town for ten years. Apart from anæmia, she was well and active up to a fortnight previous to her death. Two days before the onset of her illness she spent some hours in a valley which was subsequently found to harbour large numbers of hibernating larval and adult anopheline mosquitoes, but it is more than probable that she had become infected before this date, as anopheline mosquitoes are known to occur in one of the parks and the country round Liverpool where she was accustomed to walk. No suspicions were entertained as to the nature of her illness, and she died two hours after admission to the Liverpool Royal Infirmary on the fourteenth day from the onset of symptoms. Beyond considerable enlargement of the spleen, which was noted to be "dark, rather like malaria," the naked-eye appearances of the organs after death presented no characteristic features, and it was only on microscopic examination of blood-films and smears from the bone marrow and spleen that the nature of the case became evident. Organisms resembling degenerated crescents were present in the bone marrow, and in blood-films and smears from the spleen a large number of segmenting malignant tertian parasites were discovered. Specimens showing crescents

ucnting parasites were exhibited at the labora-
eting (see p. 26) of the Royal Society of Tropical
and Hygiene in London. Subsequent examina-
additional material showed numerous crescents
one marrow and a moderate number in the
nd blood smears. The differential count of a
rtem blood-film gave only 10 per cent. of
phonuclear cells, 28·2 per cent. lymphocytes,
per cent. mononuclears. The diagnosis of
it tertian malaria may therefore be regarded
dantly proved; that the case was indigenous
its of no question, and it is a matter of fair
that the mosquito from which infection was
had itself become infected from one of the
ctims of malignant tertian malaria who have
in this country from abroad.

gh, as is remarked by the authors, it is
that this is not the only case of malignant
alaria that has recently occurred in England,
atic conditions are such that it is unlikely that
the kind are, or ever will be, other than
nal. Lieutenant-Colonel S. P. James, I.M.S.,
some specimens to illustrate true indigenous
at the laboratory meeting to which we have
. Even in France, under far more favour-
imatic circumstances, very few cases of
us malignant tertian infection have so far
ported. Rouband[1] has referred to isolated
infection, and slight epidemics of locally
malaria have been recently notified from
parts of France; usually the infection was with
ium vivax, but he states that in some cases
arum was equally the cause. Also Lagrifoul
ard[2] record a locally acquired case due to
with *P. falciparum*. These authors remark
presence of locally acquired malignant tertian
in France should occasion no surprise, since it
that in Macedonia it spreads in regions where
mer and autumn are not warmer than in the
Mediterranean region. Further, it was reported
at a Plenary Session of the Sanitary Con-
of the Allied Powers held in Paris in March,
t of one group of 170 cases of malaria locally
ed in France during the summer and autumn
five were infections with *P. falciparum*. It
be observed that the heavy incidence of
it tertian malaria in Macedonia occurs at a
considerably south of the southern limits of
and, notwithstanding the statement quoted
is unlikely that the heat of summer on the
ittoral approaches in length or severity that of
ma and Vardar valleys.

METABOLISM OF INFANTS AND YOUNG CHILDREN.

onnexion between abnormal stools in infants
ctive fat-digestion has long been a subject of
mong pædiatricians. Any approach to accurate
ons of the alterations from the normal fat-
of fæces has been hindered by a lack of standard
or healthy subjects which could be accepted as
al in England. In the last two years a couple
tant contributions to this subject have appeared,
in America and the other in England. During
Emmett Holt, working with Angelia M. Courtney
len L. Fales, gave the results of laborious
tions on the normal and abnormal fat-
ism of infants and young children in a
of papers first appearing in the *American
of Children's Diseases*, and now reprinted
in the volume of Studies from the Rockefeller
for Medical Research for 1920 (vol. xxxiv.).
with the examination of the stools of
er of healthy breast-fed infants, the authors
at, although over 90 per cent. of the food-fat
orbed, the dried fæces contained on an average
as 34·5 per cent. of fat. Of this fæcal fat
er cent. was in the form of neutral fat, and
per cent. in the form of soap. In healthy babies fed on modifications of cow's milk the digestion of fat appeared to be about as satisfactorily carried out as in the breast-fed, though such slight differences as were found were in favour of the latter. Constipation made very little difference to the proportion or splitting of the fæcal fat, but in the presence of diarrhœa the amount of fat wasted in the stools was increased and the proportion of soaps lowered, as might be expected with hurried and imperfect digestion. In the third and fourth of their papers the authors investigated the fat-metabolism of older children. On a diet of milk only, or of milk and cereal, the amount of fat in the stools was lower than that of the infants, but still reached a figure of 30 per cent. On a mixed diet this proportion was lessened to 18–20 per cent. This figure still seems a high one if we compare it with the 14·5 per cent. found in the case reported by Garrod and Hurtley,[1] of a normal boy on a mixed diet rich in fat. In rachitic children the American authors found a slightly increased fat loss, and in chronic intestinal indigestion the wastage was considerably increased. Finally, the important question of substitutes for butter-fat was considered. It was found that nut-butter and corn-oil were both well absorbed, and that to a considerable degree they may be safely substituted for the more expensive milk-fat. The authors are careful (on the evidence submitted we might almost say scrupulous) to state that vegetable fats must never be allowed entirely to replace the animal fat of the diet. How much of the latter must be taken to provide the necessary amount of fat-soluble vitamine they hazard no opinion. Another valuable paper dealing with the same subject was published by H. S. Hutchison[2] in April, 1920. This author, investigating independently in Glasgow, reaches figures closely agreeing with the American results as regards the absorption and digestion of fat in infants and young children. He finds that in rickets the excess loss of fat daily compared to that in healthy subjects averages 0·6 g., an amount which is sufficient to affect nutrition. In infantile atrophy he found no true defect in fat-absorption. He lays great stress upon the importance of ascertaining the daily weight of the stools before attempting to judge whether fat-absorption is normal or defective. It is evident that percentage estimations alone may lead to wrong conclusions in this matter, and that before a balance can be struck, the daily intake and output of fat must both be known. These two sets of investigations, agreeing closely with one another, certainly serve to establish a standard set of figures for the fat-metabolism of normal infants.

"SNOW-BLINDNESS."

A PAPER by Lieutenant-Commander E. L. Atkinson, read before the War Section of the Royal Society of Medicine (see p. 24), throws some fresh light on this subject, gained partly during service with Scott's Antarctic Expedition, 1911–1913, and partly in North Russia in 1919. As is well known, the ordinary symptoms are photophobia, lacrymation, and chemosis, coming on after an interval of several hours. In Commander Atkinson's experience the symptoms came on more rapidly, especially on entering a tent where a primus stove was burning. They also included slight hyperæmia of the retina, and later small corneal ulcers. Recovery, however, was the rule. The rays which cause "snow-blindness" are generally admitted to be the ultra-violet ones, which, being absorbed almost entirely by the cornea and lens, can in themselves have no direct action on the retina. Their action, however, was intensified by the excessive illumination of the Antarctic region, due to the countless ice crystals reflecting light into the eye from all directions. Exposure of the eyes for as little as 15 minutes to these conditions was enough to cause the symptoms. In certain cases another symptom followed—namely, diplopia. This was probably due to the excessive strain on the external ocular muscles caused by the unusual diffusion of light, resulting in the absence of any

pulse 140, and respirations 42. Smears from the discharge showed many Gram-negative intracellular diplococci. The abscess was opened, and similar organisms were found in the pus. A culture from the blood also showed them. Under rest the pains in the joints subsided, as did the abdominal distension. The spleen could then be felt to extend 2 inches below the ribs. The cardiac murmur became harsh and intensified, and death took place on the seventh day in hospital. The necropsy showed greenish-yellow cauliflower vegetations on the free borders of the mitral valve. Cover-glass preparations from the valve revealed Gram-negative diplococci.

Gonococcal endocarditis in children is rare. Satterthwaite in 100 cases of endocarditis in New York children found only one due to the gonococcus. Abscess in the subcutaneous tissue or in muscle has been observed in a few cases of gonorrhœa. Dr. Dwyer suggests that the abscess in the sacral region in his case was the result of localisation of organisms from the blood stream due to lowered resistance in that area from pressure. The usual features of gonococcal endocarditis are irregular intermittent fever, chills, and anæmia, and do not differ from those observed in endocarditis due to other organisms. An increase in the intensity of the murmur from day to day, such as was found in the present case, has been noted by several observers.

THE EAR AS PROTOTYPE OF THE TORPEDO.

Dr. H. Hartridge, in the *Journal of Physiology* (vol. liv., No. 4), offers an ingenious suggestion to account for the well-known association in the inner ear of such diverse and differently constituted apparatus as the semicircular canals, the otolith mechanisms on the one hand, and the cochlea with its adjuvant fenestræ, fluids, and middle-ear chain of ossicles on the other. The suggestion is that the mammalian organ subserved in the ancestors of mammals the function of perceiving depth below water surface, and was therefore associated with the semicircular canals and otolith organs in the identification of position and direction of travel. As the author shows, there is a close mechanical analogy between the auditory apparatus of mammals and the depth-controlling gear of the naval torpedo. In the latter are two mechanisms which operate together to control the depth at which the projectile shall travel beneath the surface of the water. 1. A pendulum under the influence of gravity records any deflection that the long axis of the torpedo may make with the horizontal, and if such deflection exists it turns the horizontal rudders in such a direction that the deflection tends to be corrected. 2. A hydrostatic membrane, a sheet-rubber diaphragm, situated in the side of the torpedo in contact with the water outside and on the inside with the air-filled interior. As the torpedo gets deeper in the water the hydrostatic pressure tends to press the diaphragm inwards against a resisting spring. If the torpedo is at the correct depth at which it is required to travel, the hydrostatic pressure produces a force on the diaphragm that is just balanced by the force exerted in the opposite direction by the spring; but if the torpedo gets too deep or too shallow the forces no longer balance, and the diaphragm is pressed inwards or allowed to move outwards respectively, and this causes appropriate deflection of the rudders. If pendulum and hydrostatic membrane operate together, it is found by experiment that the one eliminates the tendency to deflection caused by the other, and the torpedo is thus caused to travel along a straight path at a given distance under the surface. Applying these results to the fish, the latter for the proper direction of its path in three dimensions in space would require at least a mechanism to give information concerning depth below surface and one to be influenced by gravity, and therefore to show deflection from the horizontal axis. The latter mechanism is identified as the otolith organ. Dr. Hartridge suggests that the tympanum, middle ear, and cochlea are to be identified as the depth-recording mechanisms, the tympanum being the counterpart of the rubber hydrostatic membrane of the torpedo, the ear ossicles the counterpart of the levers which transmit the motion of the diaphragm under varying hydrostatic pressure to the rudder-control mechanism, the stapedius muscle acting as the spring which in the torpedo balances the forces produced in the diaphragm by the hydrostatic pressure. Any mechanism for recording changes in hydrostatic pressure has a fluid—e.g., water on one side of the diaphragm, and a readily compressible fluid, gas, or air on the other side, with arrangements for renewing the air, as it is liable to be absorbed. In shallow water fish and in most reptilia the renewal of air in the middle ear is readily affected by the fish coming to the surface of the water and taking in the air and equalising the tension by the mouth and Eustachian tubes. In some fish the air in the swim bladder is renewed in a similar way. In certain fish living below the surface there is a special connexion with the gas-secreting gland, the swim bladder. In many osseous fishes this is effected through a connexion between the swim bladder and the middle ear by means of a tube, or the swim bladder itself forms the chamber, the change in volume of which (with change of depth below surface) brings about movements in the mechanism which connects with the middle ear, as in carp, loche, and sleat-fish. The remarkable mechanism of articulated bones which connects the ear and the swim bladder in the Siluridæ seems to be associated with the perception of depth and not with audition—and is for measuring air-bladder volume under changes of hydrostatic pressure. The view is advanced that the auditory apparatus of mammalia, which is represented by the cochlea, fenestræ, ossicles, and tympanum, once formed in their ancestors an apparatus for perceiving not sound vibrations but the depths below sea-level. Granting this, it would explain why the cochlea, semicircular canals, and the otolith organs are associated together anatomically, and have a common nerve; and if the cochlea perceives depth below surface all three will be directly concerned with the perception of position and the control of direction.

INDIGENOUS MALIGNANT TERTIAN MALARIA.

A CASE of malignant tertian malaria contracted by a resident of Liverpool and ending fatally was reported by Professor E. E. Glynn and Dr. J. C. Matthews at a recent meeting of the Liverpool Medical Institution. The case is of unusual importance on more than one ground. Not only is it the first recorded instance of indigenous malignant tertian malaria occurring in England since our knowledge of the differentiation of the various forms of malaria has attained its present high degree of precision, but the disease was contracted in a district considerably to the north of the areas where indigenous malaria has in past times been prevalent. Further, the case stands alone as the only reported instance of fatal indigenous malaria of recent years. The patient was a girl, aged 18; she was a native of Liverpool, and had lived in the same house in the town for ten years. Apart from anæmia, she was well and active up to a fortnight previous to her death. Two days before the onset of her illness she spent some hours in a valley which was subsequently found to harbour large numbers of hibernating larval and adult anopheline mosquitoes, but it is more than probable that she had become infected before this date, as anopheline mosquitoes are known to occur in one of the parks and the country round Liverpool where she was accustomed to walk. No suspicions were entertained as to the nature of her illness, and she died two hours after admission to the Liverpool Royal Infirmary on the fourteenth day from the onset of symptoms. Beyond considerable enlargement of the spleen, which was noted to be "dark, rather like malaria," the naked-eye appearances of the organs after death presented no characteristic features, and it was only on microscopic examination of blood-films and smears from the bone marrow and spleen that the nature of the case became evident. Organisms resembling degenerated crescents were present in the bone marrow, and in blood-films and smears from the spleen a large number of segmenting malignant tertian parasites were discovered. Specimens showing crescents

and segmenting parasites were exhibited at the laboratory meeting (see p. 26) of the Royal Society of Tropical Medicine and Hygiene in London. Subsequent examination of additional material showed numerous crescents in the bone marrow and a moderate number in the spleen and blood smears. The differential count of a post-mortem blood-film gave only 10 per cent. of polymorphonuclear cells, 28·2 per cent. lymphocytes, and 61·4 per cent. mononuclears. The diagnosis of malignant tertian malaria may therefore be regarded as abundantly proved; that the case was indigenous also admits of no question, and it is a matter of fair inference that the mosquito from which infection was derived had itself become infected from one of the many victims of malignant tertian malaria who have arrived in this country from abroad.

Although, as is remarked by the authors, it is probable that this is not the only case of malignant tertian malaria that has recently occurred in England, our climatic conditions are such that it is unlikely that cases of the kind are, or ever will be, other than exceptional. Lieutenant-Colonel S. P. James, I.M.S., showed some specimens to illustrate true indigenous malaria at the laboratory meeting to which we have referred. Even in France, under far more favourable climatic circumstances, very few cases of indigenous malignant tertian infection have so far been reported. Roubaud[1] has referred to isolated cases of infection, and slight epidemics of locally acquired malaria have been recently notified from various parts of France; usually the infection was with *Plasmodium vivax*, but he states that in some cases *P. falciparum* was equally the cause. Also Lagriffoul and Picard[2] record a locally acquired case due to infection with *P. falciparum*. These authors remark that the presence of locally acquired malignant tertian malaria in France should occasion no surprise, since it is known that in Macedonia it spreads in regions where the summer and autumn are not warmer than in the French Mediterranean region. Further, it was reported by Roux at a Plenary Session of the Sanitary Conference of the Allied Powers held in Paris in March, 1919, that of one group of 170 cases of malaria locally contracted in France during the summer and autumn of 1917, five were infections with *P. falciparum*. It should be observed that the heavy incidence of malignant tertian malaria in Macedonia occurs at a latitude considerably south of the southern limits of France, and, notwithstanding the statement quoted above, it is unlikely that the heat of summer on the French littoral approaches in length or severity that of the Struma and Vardar valleys.

FAT-METABOLISM OF INFANTS AND YOUNG CHILDREN.

THE connexion between abnormal stools in infants and defective fat-digestion has long been a subject of debate among pædiatricians. Any approach to accurate estimations of the alterations from the normal fat-content of fæces has been hindered by a lack of standard figures for healthy subjects which could be accepted as the normal in England. In the last two years a couple of important contributions to this subject have appeared, the first in America and the other in England. During 1919 L. Emmett Holt, working with Angelia M. Courtney and Helen L. Fales, gave the results of laborious investigations on the normal and abnormal fat-metabolism of infants and young children in a series of papers first appearing in the *American Journal of Children's Diseases*, and now reprinted together in the volume of Studies from the Rockefeller Institute for Medical Research for 1920 (vol. xxxiv.). Starting with the examination of the stools of a number of healthy breast-fed infants, the authors found that, although over 90 per cent. of the food-fat was absorbed, the dried fæces contained on an average as much as 34·5 per cent. of fat. Of this fæcal fat 15–20 per cent. was in the form of neutral fat, and about 50 per cent. in the form of soap. In healthy babies fed on modifications of cow's milk the digestion of fat appeared to be about as satisfactorily carried out as in the breast-fed, though such slight differences as were found were in favour of the latter. Constipation made very little difference to the proportion or splitting of the fæcal fat, but in the presence of diarrhœa the amount of fat wasted in the stools was increased and the proportion of soaps lowered, as might be expected with hurried and imperfect digestion. In the third and fourth of their papers the authors investigated the fat-metabolism of older children. On a diet of milk only, or of milk and cereal, the amount of fat in the stools was lower than that of the infants, but still reached a figure of 30 per cent. On a mixed diet this proportion was lessened to 18–20 per cent. This figure still seems a high one if we compare it with the 14·5 per cent. found in the case reported by Garrod and Hurtley,[1] of a normal boy on a mixed diet rich in fat. In rachitic children the American authors found a slightly increased fat loss, and in chronic intestinal indigestion the wastage was considerably increased. Finally, the important question of substitutes for butter-fat was considered. It was found that nut-butter and corn-oil were both well absorbed, and that to a considerable degree they may be safely substituted for the more expensive milk-fat. The authors are careful (on the evidence submitted we might almost say scrupulous) to state that vegetable fats must never be allowed entirely to replace the animal fat of the diet. How much of the latter must be taken to provide the necessary amount of fat-soluble vitamine they hazard no opinion. Another valuable paper dealing with the same subject was published by H. S. Hutchison[2] in April, 1920. This author, investigating independently in Glasgow, reaches figures closely agreeing with the American results as regards the absorption and digestion of fat in infants and young children. He finds that in rickets the excess loss of fat daily compared to that in healthy subjects averages 0·6 g., an amount which is sufficient to affect nutrition. In infantile atrophy he found no true defect in fat-absorption. He lays great stress upon the importance of ascertaining the daily weight of the stools before attempting to judge whether fat-absorption is normal or defective. It is evident that percentage estimations alone may lead to wrong conclusions in this matter, and that before a balance can be struck, the daily intake and output of fat must both be known. These two sets of investigations, agreeing closely with one another, certainly serve to establish a standard set of figures for the fat-metabolism of normal infants.

"SNOW-BLINDNESS."

A PAPER by Lieutenant-Commander E. L. Atkinson, read before the War Section of the Royal Society of Medicine (see p. 24), throws some fresh light on this subject, gained partly during service with Scott's Antarctic Expedition, 1911–1913, and partly in North Russia in 1919. As is well known, the ordinary symptoms are photophobia, lacrymation, and chemosis, coming on after an interval of several hours. In Commander Atkinson's experience the symptoms came on more rapidly, especially on entering a tent where a primus stove was burning. They also included slight hyperæmia of the retina, and later small corneal ulcers. Recovery, however, was the rule. The rays which cause "snow-blindness" are generally admitted to be the ultra-violet ones, which, being absorbed almost entirely by the cornea and lens, can in themselves have no direct action on the retina. Their action, however, was intensified by the excessive illumination of the Antarctic region, due to the countless ice crystals reflecting light into the eye from all directions. Exposure of the eyes for as little as 15 minutes to these conditions was enough to cause the symptoms. In certain cases another symptom followed—namely, diplopia. This was probably due to the excessive strain on the external ocular muscles caused by the unusual diffusion of light, resulting in the absence of any

pulse 140, and respirations 42. Smears from the discharge showed many Gram-negative intracellular diplococci. The abscess was opened, and similar organisms were found in the pus. A culture from the blood also showed them. Under rest the pains in the joints subsided, as did the abdominal distension. The spleen could then be felt to extend 2 inches below the ribs. The cardiac murmur became harsh and intensified, and death took place on the seventh day in hospital. The necropsy showed greenish-yellow cauliflower vegetations on the free borders of the mitral valve. Cover-glass preparations from the valve revealed Gram-negative diplococci.

Gonococcal endocarditis in children is rare. Satterthwaite in 100 cases of endocarditis in New York children found only one due to the gonococcus. Abscess in the subcutaneous tissue or in muscle has been observed in a few cases of gonorrhœa. Dr. Dwyer suggests that the abscess in the sacral region in his case was the result of localisation of organisms from the blood stream due to lowered resistance in that area from pressure. The usual features of gonococcal endocarditis are irregular intermittent fever, chills, and anæmia, and do not differ from those observed in endocarditis due to other organisms. An increase in the intensity of the murmur from day to day, such as was found in the present case, has been noted by several observers.

THE EAR AS PROTOTYPE OF THE TORPEDO.

Dr. H. Hartridge, in the *Journal of Physiology* (vol. liv., No. 4), offers an ingenious suggestion to account for the well-known association in the inner ear of such diverse and differently constituted apparatus as the semicircular canals, the otolith mechanisms on the one hand, and the cochlea with its adjuvant fenestræ, fluids, and middle-ear chain of ossicles on the other. The suggestion is that the mammalian organ subserved in the ancestors of mammals the function of perceiving depth below water surface, and was therefore associated with the semicircular canals and otolith organs in the identification of position and direction of travel. As the author shows, there is a close mechanical analogy between the auditory apparatus of mammals and the depth-controlling gear of the naval torpedo. In the latter are two mechanisms which operate together to control the depth at which the projectile shall travel beneath the surface of the water. 1. A pendulum under the influence of gravity records any deflection that the long axis of the torpedo may make with the horizontal, and if such deflection exists it turns the horizontal rudders in such a direction that the deflection tends to be corrected. 2. A hydrostatic membrane, a sheet-rubber diaphragm, situated in the side of the torpedo in contact with the water outside and on the inside with the air-filled interior. As the torpedo gets deeper in the water the hydrostatic pressure tends to press the diaphragm inwards against a resisting spring. If the torpedo is at the correct depth at which it is required to travel, the hydrostatic pressure produces a force on the diaphragm that is just balanced by the force exerted in the opposite direction by the spring; but if the torpedo gets too deep or too shallow the forces no longer balance, and the diaphragm is pressed inwards or allowed to move outwards respectively, and this causes appropriate deflection of the rudders. If pendulum and hydrostatic membrane operate together, it is found by experiment that the one eliminates the tendency to deflection caused by the other, and the torpedo is thus caused to travel along a straight path at a given distance under the surface. Applying these results to the fish, the latter for the proper direction of its path in three dimensions in space would require at least a mechanism to give information concerning depth below surface and one to be influenced by gravity, and therefore to show deflection from the horizontal axis. The latter mechanism is identified as the otolith organ. Dr. Hartridge suggests that the tympanum, middle ear, and cochlea are to be identified as the depth-recording mechanisms, the tympanum being the counterpart of the rubber hydrostatic membrane of the torpedo, the ear ossicles the counterpart of the levers which transmit the motion of the diaphragm under varying hydrostatic pressure to the rudder-control mechanism, the stapedius muscle acting as the spring which in the torpedo balances the forces produced in the diaphragm by the hydrostatic pressure. Any mechanism for recording changes in hydrostatic pressure has a fluid—e.g., water on one side of the diaphragm, and a readily compressible fluid, gas, or air on the other side, with arrangements for renewing the air, as it is liable to be absorbed. In shallow water fish and in most reptilia the renewal of air in the middle ear is readily affected by the fish coming to the surface of the water and taking in the air and equalising the tension by the mouth and Eustachian tubes. In some fish the air in the swim bladder is renewed in a similar way. In certain fish living below the surface there is a special connexion with the gas-secreting gland, the swim bladder. In many osseous fishes this is effected through a connexion between the swim bladder and the middle ear by means of a tube, or the swim bladder itself forms the chamber, the change in volume of which (with change of depth below surface) brings about movements in the mechanism which connects with the middle ear, as in carp, loche, and sleat-fish. The remarkable mechanism of articulated bones which connects the ear and the swim bladder in the Siluridæ seems to be associated with the perception of depth and not with audition—and is for measuring air-bladder volume under changes of hydrostatic pressure. The view is advanced that the auditory apparatus of mammalia, which is represented by the cochlea, fenestræ, ossicles, and tympanum, once formed in their ancestors an apparatus for perceiving not sound vibrations but the depths below sea-level. Granting this, it would explain why the cochlea, semicircular canals, and the otolith organs are associated together anatomically, and have a common nerve; and if the cochlea perceives depth below surface all three will be directly concerned with the perception of position and the control of direction.

INDIGENOUS MALIGNANT TERTIAN MALARIA.

A CASE of malignant tertian malaria contracted by a resident of Liverpool and ending fatally was reported by Professor E. E. Glynn and Dr. J. C. Matthews at a recent meeting of the Liverpool Medical Institution. The case is of unusual importance on more than one ground. Not only is it the first recorded instance of indigenous malignant tertian malaria occurring in England since our knowledge of the differentiation of the various forms of malaria has attained its present high degree of precision, but the disease was contracted in a district considerably to the north of the areas where indigenous malaria has in past times been prevalent. Further, the case stands alone as the only reported instance of fatal indigenous malaria of recent years. The patient was a girl, aged 18; she was a native of Liverpool, and had lived in the same house in the town for ten years. Apart from anæmia, she was well and active up to a fortnight previous to her death. Two days before the onset of her illness she spent some hours in a valley which was subsequently found to harbour large numbers of hibernating larval and adult anopheline mosquitoes, but it is more than probable that she had become infected before this date, as anopheline mosquitoes are known to occur in one of the parks and the country round Liverpool where she was accustomed to walk. No suspicions were entertained as to the nature of her illness, and she died two hours after admission to the Liverpool Royal Infirmary on the fourteenth day from the onset of symptoms. Beyond considerable enlargement of the spleen, which was noted to be "dark, rather like malaria," the naked-eye appearances of the organs after death presented no characteristic features, and it was only on microscopic examination of blood-films and smears from the bone marrow and spleen that the nature of the case became evident. Organisms resembling degenerated crescents were present in the bone marrow, and in blood-films and smears from the spleen a large number of segmenting malignant tertian parasites were discovered. Specimens showing crescents

and segmenting parasites were exhibited at the laboratory meeting (see p. 26) of the Royal Society of Tropical Medicine and Hygiene in London. Subsequent examination of additional material showed numerous crescents in the bone marrow and a moderate number in the spleen and blood smears. The differential count of a post-mortem blood-film gave only 10 per cent. of polymorphonuclear cells, 28·2 per cent. lymphocytes, and 61·4 per cent. mononuclears. The diagnosis of malignant tertian malaria may therefore be regarded as abundantly proved; that the case was indigenous also admits of no question, and it is a matter of fair inference that the mosquito from which infection was derived had itself become infected from one of the many victims of malignant tertian malaria who have arrived in this country from abroad.

Although, as is remarked by the authors, it is probable that this is not the only case of malignant tertian malaria that has recently occurred in England, our climatic conditions are such that it is unlikely that cases of the kind are, or ever will be, other than exceptional. Lieutenant-Colonel S. P. James, I.M.S., showed some specimens to illustrate true indigenous malaria at the laboratory meeting to which we have referred. Even in France, under far more favourable climatic circumstances, very few cases of indigenous malignant tertian infection have so far been reported. Roubaud[1] has referred to isolated cases of infection, and slight epidemics of locally acquired malaria have been recently notified from various parts of France; usually the infection was with *Plasmodium vivax*, but he states that in some cases *P. falciparum* was equally the cause. Also Lagriffoul and Picard[2] record a locally acquired case due to infection with *P. falciparum*. These authors remark that the presence of locally acquired malignant tertian malaria in France should occasion no surprise, since it is known that in Macedonia it spreads in regions where the summer and autumn are not warmer than in the French Mediterranean region. Further, it was reported by Roux at a Plenary Session of the Sanitary Conference of the Allied Powers held in Paris in March, 1919, that of one group of 170 cases of malaria locally contracted in France during the summer and autumn of 1917, five were infections with *P. falciparum*. It should be observed that the heavy incidence of malignant tertian malaria in Macedonia occurs at a latitude considerably south of the southern limits of France, and, notwithstanding the statement quoted above, it is unlikely that the heat of summer on the French littoral approaches in length or severity that of the Struma and Vardar valleys.

FAT-METABOLISM OF INFANTS AND YOUNG CHILDREN.

THE connexion between abnormal stools in infants and defective fat-digestion has long been a subject of debate among pædiatricians. Any approach to accurate estimations of the alterations from the normal fat-content of fæces has been hindered by a lack of standard figures for healthy subjects which could be accepted as the normal in England. In the last two years a couple of important contributions to this subject have appeared, the first in America and the other in England. During 1919 L. Emmett Holt, working with Angelia M. Courtney and Helen L. Fales, gave the results of laborious investigations on the normal and abnormal fat-metabolism of infants and young children in a series of papers first appearing in the *American Journal of Children's Diseases*, and now reprinted together in the volume of Studies from the Rockefeller Institute for Medical Research for 1920 (vol. xxxiv.). Starting with the examination of the stools of a number of healthy breast-fed infants, the authors found that, although over 90 per cent. of the food-fat was absorbed, the dried fæces contained on an average as much as 34·5 per cent. of fat. Of this fæcal fat 15–20 per cent. was in the form of neutral fat, and about 50 per cent. in the form of soap. In healthy babies fed on modifications of cow's milk the digestion of fat appeared to be about as satisfactorily carried out as in the breast-fed, though such slight differences as were found were in favour of the latter. Constipation made very little difference to the proportion or splitting of the fæcal fat, but in the presence of diarrhœa the amount of fat wasted in the stools was increased and the proportion of soaps lowered, as might be expected with hurried and imperfect digestion. In the third and fourth of their papers the authors investigated the fat-metabolism of older children. On a diet of milk only, or of milk and cereal, the amount of fat in the stools was lower than that of the infants, but still reached a figure of 30 per cent. On a mixed diet this proportion was lessened to 18–20 per cent. This figure still seems a high one if we compare it with the 14·5 per cent. found in the case reported by Garrod and Hurtley,[1] of a normal boy on a mixed diet rich in fat. In rachitic children the American authors found a slightly increased fat loss, and in chronic intestinal indigestion the wastage was considerably increased. Finally, the important question of substitutes for butter-fat was considered. It was found that nut-butter and corn-oil were both well absorbed, and that to a considerable degree they may be safely substituted for the more expensive milk-fat. The authors are careful (on the evidence submitted we might almost say scrupulous) to state that vegetable fats must never be allowed entirely to replace the animal fat of the diet. How much of the latter must be taken to provide the necessary amount of fat-soluble vitamine they hazard no opinion. Another valuable paper dealing with the same subject was published by H. S. Hutchison[2] in April, 1920. This author, investigating independently in Glasgow, reaches figures closely agreeing with the American results as regards the absorption and digestion of fat in infants and young children. He finds that in rickets the excess loss of fat daily compared to that in healthy subjects averages 0·6 g., an amount which is sufficient to affect nutrition. In infantile atrophy he found no true defect in fat-absorption. He lays great stress upon the importance of ascertaining the daily weight of the stools before attempting to judge whether fat-absorption is normal or defective. It is evident that percentage estimations alone may lead to wrong conclusions in this matter, and that before a balance can be struck, the daily intake and output of fat must both be known. These two sets of investigations, agreeing closely with one another, certainly serve to establish a standard set of figures for the fat-metabolism of normal infants.

"SNOW-BLINDNESS."

A PAPER by Lieutenant-Commander E. L. Atkinson, read before the War Section of the Royal Society of Medicine (see p. 24), throws some fresh light on this subject, gained partly during service with Scott's Antarctic Expedition, 1911–1913, and partly in North Russia in 1919. As is well known, the ordinary symptoms are photophobia, lacrymation, and chemosis, coming on after an interval of several hours. In Commander Atkinson's experience the symptoms came on more rapidly, especially on entering a tent where a primus stove was burning. They also included slight hyperæmia of the retina, and later small corneal ulcers. Recovery, however, was the rule. The rays which cause "snow-blindness" are generally admitted to be the ultra-violet ones, which, being absorbed almost entirely by the cornea and lens, can in themselves have no direct action on the retina. Their action, however, was intensified by the excessive illumination of the Antarctic region, due to the countless ice crystals reflecting light into the eye from all directions. Exposure of the eyes for as little as 15 minutes to these conditions was enough to cause the symptoms. In certain cases another symptom followed—namely, diplopia. This was probably due to the excessive strain on the external ocular muscles caused by the unusual diffusion of light, resulting in the absence of any stimulus making for the fixation of the two eyes on a single point. Prevention is easily attained by the use of glasses, which cut off some of the light rays and all of the ultra-violet ones. Probably the most effective are Crookes's glasses No. 2, and for long expeditions they should be provided with side-pieces to cut off the lateral light. For ordinary holiday-makers, such as the fortunate people who are about to spend a few weeks in the Swiss ski-ing and skating resorts, ordinary smoked glasses will be generally found to answer the purpose sufficiently well.

PSYCHONEUROSIS, SYMPATHETIC AND ENDOCRIN.

ALL interested in psychological medicine will welcome a brochure entitled, "Functional Mental Illness and the Interdependence of the Sympathetic and Central Nervous System in Relation to the Psychoneuroses," by Dr. R. G. Rows and Dr. David Orr,[1] reprinted from the *Edinburgh Medical Journal*, the first, we believe, published by these original and devoted workers since army medical duties claimed all their energies. The present work is a courageous attempt to bring into relation the central nervous system, the sympathetic and autonomic systems, the endocrine organs with the effects of emotion and mental strain. The whole trend of the two essays is frankly appreciative of modern psychological investigation. The value of the teachings of Freud is recognised, but it does not appear from the cases recorded that orthodox Freudian psycho-analysis was practised, though it is evident they consider careful psychological investigations of repressed ideas essential for successful treatment. They point out that repressed emotions and conflicts are accompanied by disturbance of nervous function, and they outline a mechanism by which psychical trauma directly produces changes in structure, thus throwing light on the inscrutable problem of the relations between mind and matter. It is claimed that the sympathetic system is represented in the cerebral cortex, and that emotion and stress through the sympathetic affect the endocrine organs, and that these liberate hormones which affect all the bodily tissues. In this way a vicious circle may be produced. Dr. Rows deprecates the collection of symptoms under names such as dementia præcox, which he regards as a sterile procedure. Recent research shows that the body works as a whole, and three principles must be recognised: (1) the importance of the autonomic and sympathetic systems; (2) the special activities of the endocrine organs; (3) the correlation of the latter with the sympathetic system. From the concluding words of Dr. Rows's essay, as from one of Dr. Orr's opening sentences, it seems fair to infer that both authors consider that insanity could be prevented if it were properly treated in its early stages. Unfortunately, the time has not yet come when such sweeping assertions can be justified. All will agree that it is of the utmost importance to investigate and treat the earliest sign of mental disturbance, and no doubt in many cases further trouble may thereby be prevented, but there is little real evidence that any large proportion of confirmed mental disease is preventable. Admitting to the full the value of analysis in obtaining insight into the meaning of symptoms, it is a long step to conclude that the elucidation of psychological mechanisms is necessarily curative. Any such conclusion ignores innate degeneration, unstable mental constitution, the influence of toxic disturbance, and the possibility of gross disease of other organs reacting unfavourably upon nervous tissues.

Whilst optimistic teaching is much wanted in psychological medicine, and the worst that can happen is that we should sink into a laissez-faire attitude, yet true advance is always hindered by over-statement. It is surely fallacious to teach that if a patient were treated on some specific lines at the beginning all would have been well; such teaching recalls the charlatan who, called to a hopeless case, says impressively, "It is too late. ...... If I had only been called in earlier." There is abundance of evidence to show that modern psychological methods even in the most approved hands are not always successful. Pensions boards have still to give full pensions to ex-soldiers who have been discharged recovered from neurological war hospitals, and mental hospitals are still receiving the products of the most approved psychological treatment. To paraphrase Jowett's famous saying, "No treatment is infallible, not even the newest." Whether the psychoses develop from a primary condition essentially akin to that which produces the psychoneuroses is a question that remains unanswered. Dr. Orr's article is an excellent résumé of recent work, throwing light on the relation between the vegetative nervous system and the endocrine organs, and the effect of emotion upon both; but the inexperienced reader would be helped if the limitations of our knowledge were pointed out more plainly. Taken as a whole, the argument running through both papers is a timely contribution to our knowledge. It is helpful to have brought out for us so plainly the importance both of modern psychological methods of investigation and the value of the study of the sympathetic-endocrine system, and to learn that, in some measure at any rate, these can be correlated. We can, as Dr. Orr concludes, no longer regard psychoneuroses as psychic disturbances in the narrow sense employed in the past.

THE SIZE OF RED BLOOD CORPUSCLES.

IT might easily be supposed that the dried blood film had by this time yielded most of its secrets. Dr. C. Price-Jones, however, shows[1] that something fresh may yet be got from it. By careful measurements he finds that the average diameter of the red cells on first waking in the morning is about 0·5 μ less than during ordinary waking hours; it soon increases after getting up, and by about noon reaches a maximum which is maintained till bed-time. Violent exercise superimposes on this diurnal curve a sudden increase with a rapid return to normal; gentle exercise has no obvious effect. The suggestion that the corpuscles swell when the blood becomes more acid and shrink when it becomes more alkaline was confirmed by experiments in vitro in which lactic acid, CO_2, and sodium carbonate were added to defibrinated blood. Particularly striking are the changes produced by forced breathing in which the alkalinity is increased by washing out CO_2; the cells immediately shrink, and almost as quickly regain their normal size. Dr. Price-Jones suggests that the increased size of the cells in venous blood, known long since to Limbeck and Hamburger, is an ingenious arrangement whereby their passage through the lungs is delayed until the excess of CO_2 is discharged.

DERMATITIS DYSMENORRHŒICA.

IN a review of this subject Dr. Fred Wise and Dr. H. J. Parkhurst,[2] of New York, remark that ever since the article by Matzenauer and Pollitzer in 1912 on dermatitis dysmenorrhœica there has been much controversy among dermatologists as to the genuineness of this rare affection. The clinical symptoms consist in a burning sensation of the skin, accompanied by an urticaria-like swelling of a faint rose-red colour which differentiates the condition from the more intense scarlet of other inflammatory processes. Within a quarter to half an hour later a further stage of development occurs: the follicles stand out more distinctly, each being surrounded by an anæmic zone. This appearance is soon followed by an exudation of serum into the follicular orifice, and subsequently a thin yellowish-brown crust forms. A superficial desquamation about the follicles ensues, especially in the more acute cases. The follicles being close together, these vesicular areas soon coalesce to form patches of weeping dermatitis or yellow crust-covered lesions simulating traumatic excoriations. The further manifestations are either secondary or the result of involution of the lesions. Rubbing or scratching may cause superficial excoriations or slight hæmorrhages, thus intensifying the inflammatory process and causing increased exudation and crust formation. Usually the necrosis reaches no further than the rete Malpighii, and healing occurs within three or four days, but in the more severe cases the necrosis may extend deeply, resulting in the formation of hypertrophic scars and keloids. Any part of the body may be *affected, but the face is the area of predilection.* In one of Matzenauer's and Pollitzer's patients there was a coincident eruption of the lingual and buccal mucosæ. The lesions, which are almost always symmetrical in distribution, are usually round or oval on the cheeks and buttocks and linear on the extremities. The patient seen by Dr. Wise and Dr. Parkhurst was a woman, aged 30, who suffered from dysmenorrhœa, each menstrual period being accompanied by a regularly recurrent eruption manifested by œdema, erythema, follicular hæmorrhage, crusting, and pigmentation. Between the menstrual periods and in pregnancy the eruption was in abeyance. The writers were convinced that malingering played no part in the causation of the dermatosis.

BEETHOVEN'S DISEASES.

IN a paper published under this title on the 150th anniversary of Beethoven's birth Dr. Schweisheimer,[1] of Munich, discusses the pathological history of Beethoven. His tragic ear disease, which dated back to the age of 28, and probably earlier, first involved the left and then the right ear. At an early date he was unable to hear the high tones of instruments or singing at any distance. This fact, combined with the progressive character of the disease, indicates that the ear affection was not otosclerosis, as might at first be supposed, but a disorder of the internal ear, of which early lowering of the upper tone limits is characteristic. As there was no history of attacks of giddiness or other disturbance of equilibrium the cochlear nerve must have been principally affected. There was no indication of the middle ear having been primarily attacked. The auditory centre in the brain was not involved. The cause of the deafness can only be conjectured. There is nothing in Beethoven's history pointing to an infectious origin for the acoustic neuritis, and toxic and traumatic factors could be excluded. Dr. Schweisheimer suggests that there was a constitutional weakness of the auditory nerve, which developed as time went on, and was possibly due, in part at least, to hereditary taint. Beethoven's father and maternal grandmother were drinkers, and his mother is said to have died of consumption. There was no history of deafness in the family. Apart from minor ailments, such as a whitlow, which interfered with playing the piano, and a moderate degree of myopia, Beethoven began to suffer at a comparatively early date from symptoms of cirrhosis of the liver, for which indulgence in punch was probably responsible. In his later years œdema of the legs and ascites developed, giving rise to dyspnœal attacks from pressure on the diaphragm. Paracentesis abdominis was performed on four occasions, but relief was only temporary, and death took place at the age of 56. The necropsy, which was performed by Dr. Johannes Wagner, of the Vienna Pathological Museum, showed atrophy of the auditory nerves and atrophic cirrhosis of the liver.

THE executive committee of the War Emergency Fund of the Royal Medical Benevolent Fund announces that it is now prepared to make grants for the daughters of medical men in circumstances similar to those which have entitled applicants to grants for the education of their sons. Applications for grants should be made to the honorary secretary, War Emergency Fund, 11, Chandos-street, Cavendish-square, London, W. 1. The Fund has made several substantial grants to defray in whole or in part the school fees of the sons of medical men who, after resuming civil practice, find themselves in temporary financial difficulty owing to war service.

FINANCIAL POSITION OF HOSPITALS.

A CONFERENCE of the Representatives of the Honorary Medical Staffs of Voluntary Hospitals was held on Dec. 21st, 1920, at the Royal Society of Medicine, under the chairmanship of Sir JAMES GALLOWAY, senior physician to Charing Cross Hospital. The conference arose out of the action of the Minister of Health in appointing a Committee to inquire into the financial position of the voluntary hospitals of the country, when withdrawing or modifying Clause 11 in the Ministry of Health (Miscellaneous Provisions) Bill, which would have enabled county councils to take over the Poor-law infirmaries and run them as general hospitals at the expense of the ratepayers. The conference was called by the British Medical Association.

The first resolution before the conference was put by Mr. BISHOP HARMAN, Chairman of the Hospitals Committee of the British Medical Association, and was seconded by Sir HENRY DAVY. The motion after verbal alteration ran as follows:—

> That this conference of the staffs of voluntary hospitals called by the British Medical Association desires to record its belief that the voluntary method of administration of the voluntary hospitals of the country is to the advantage of the public, of medical science, and of the medical profession, and that it should be maintained.

The motion was supported generally by Sir HAMILTON BALLANCE (Norfolk and Norwich Hospital), who, however, asked whether institutions had been taken into account in the motion which received subsidies from the State for specific purposes, such as education grants or payments from the National Insurance Commission and Ministry of Pensions.

Mr. F. W. V. COLLINSON (Preston Royal Infirmary), pointed out that the reception of assistance to conduct venereal clinics or to attend insured or pensioned persons did not affect the voluntary system. He considered that the voluntary system was not affected by payments from those who could afford to pay.

Dr. ASTLEY V. CLARKE (Leicester Royal Infirmary) described the exact position of Leicester, where the voluntary system was keeping the great general hospital of the town solvent because it was being worked with intelligent regard for the nature of the population.

Mr. W. S. DICKIE (North Riding Infirmary) also spoke in favour of the voluntary principle.

Flat opposition was expressed to the motion and to the whole voluntary system by Dr. PETER MACDONALD of York, who found the voluntary system, as founded on charity, to be against the sentiments of the age, and who, moreover, believed it to be impossible that such a system should continue long under existing financial conditions.

Mr. L. P. GAMGEE (Birmingham General Hospital) sought the definition of what was a voluntary hospital in much the same terms as those which Sir Hamilton Ballance employed, while Dr. T. SANSOME (West Bromwich), impressed with the virtues of the voluntary system, thought that the financial arguments were against it.

Mr. BISHOP HARMAN having explained that in his motion he did not contemplate that State contributions affected the voluntary system, the resolution was put to the meeting and carried by some 150 votes to 4.

A second motion, standing in the name of Mr. A. E. MORISON, of the Durham County Hospital, registered the view of the meeting that necessitous persons should continue to be treated free. This was agreed to without dissentients, and the same lucky fate met the motion in Mr. BISHOP HARMAN'S name declaring it undesirable that voluntary hospitals should be subsidised by local rating authorities, "except in so far as payment is made for the examination and care of patients for whom these authorities are responsible."

A fourth motion standing in Mr. BISHOP HARMAN'S name was to the effect that in times of financial difficulty it is desirable that the central Government should subsidise voluntary hospitals, and that such subsidy in the case of any individual hospital should take the form of a contribution proportional to the income received by the hospital from voluntary and other contributions. The subsidies here proposed should be made through some central hospital fund.

---

[1] Münchener Medizinische Wochenschrift, Dec. 17th, 1920.

A debate arose here over an amendment, which was subsequently lost, proposed by Dr. R. A. BOLAM, Chairman of the Council of the British Medical Association. Dr. Bolam thought that it would be advisable to specify the objects for which State grants were required, and proposed that these grants should be "for training of medical practitioners and nurses and, by loan, for extension of hospital facilities." The amendment was sympathetically considered by the meeting, but was eventually lost by an almost unanimous vote, the original motion being agreed to.

The conference next registered its view—

> That a greatly extended support for voluntary hospitals should be sought from employers and insurance companies, seeing that they benefit largely, both directly and indirectly, by the services of the voluntary hospitals.

Dr. J. R. ROBERTSON (Ashton-under-Lyne Infirmary) then brought forward a motion—

> That every in-patient of a voluntary hospital should make a weekly contribution towards the cost of *maintenance* therein; in the case of insured persons this charge should be met by the *Ministry of Health.*

The first part of this motion was amended with the qualification, after the word patient, "who is not a necessitous person," and in this form the motion was agreed to.

A motion standing in the name of the Durham County Hospital was brought forward by Mr. A. E. MORISON to the following effect:—

> That this conference considers that the contributory method of subscription is the *only* one possible under the industrial conditions of the *North of England.* In view, however, of the increased cost of maintenance, &c., it considers that the contributory rates paid by workmen should be materially increased.

This met with approval, as did one proposed by Dr. MURRAY BLIGH (David Lewis Northern Hospital) to the following effect:—

> That it is desirable that voluntary hospitals, after securing sufficient accommodation for the necessitous poor, should make arrangements for the reception of patients who are able to pay for the cost of their maintenance and treatment in whole or in part.

A further resolution was moved from the David Lewis Northern Hospital, Liverpool, providing—

> That no fixed rate of payment for professional services rendered to such patients should be established, the fees so payable to remain, as at present, a matter of arrangement between patient, family physician, and consultant.

This resolution was carried.

Dr. ASTLEY CLARKE then proposed the following motion:—

> That the logical position for the members of the honorary medical staffs of all voluntary hospitals to take up in the event of decisions being taken which would lead to patients paying, in part or in whole, the hospital maintenance fees, either individually or by some contributory method, or with the addition of rate aid or State aid, or by a combination of two or more of these methods, is that a percentage of all such payments should be passed into a fund which can be allocated in any manner which such honorary medical staff may determine.

The motion was founded upon suggestions made by the British Medical Association as to the uses of a staff fund, and met with favour.

In conclusion, the meeting decided that another conference should be summoned, when it seemed necessary to the Hospitals Committee of the British Medical Association.

FROM the beginning of 1921 the annual Fellowship dues of the American Medical Association are raised from $5 to $6, an increase 20 *per cent.* The subscription carries with it the right to receive the *Journal of the A.M.A.*, the income from which supports the Association's activities in the interest of the medical profession and the public, such as the work of the Council on Pharmacy and Chemistry, of the Chemical Laboratory, of the Council on Medical Education and Hospitals, of the Council on Health and Public Instruction, and of the Biographical and Propaganda Departments.

TUBERCULOSIS.

Decline of Tuberculosis in Birmingham.

THE report issued by Dr. G. B. Dixon on tuberculosis in Birmingham strikes a happy mean between the flamboyant note of the pre-war era, when much was written and talked about the conquest of consumption, and the jeremiads on tuberculosis so familiar at the present time. Birmingham achieved in 1919 the lowest tuberculosis death-rate on record, the figures being 1188 deaths from all forms of tuberculosis, equivalent to a mortality-rate of 1·28 per 1000. The number of notifications was 3116—the lowest since notification was introduced. Thus there is good reason for Dr. Dixon's claim: "We are now getting fewer deaths than before the war, and we are getting far fewer new cases." Dr. Dixon carefully avoids the tempting claim that the decline of tuberculosis is mainly due to direct anti-tuberculosis measures; it is, no doubt, due to many factors, several of which are still more or less obscure. But it is evident from his report that the campaign against tuberculosis in Birmingham is whole-hearted and multi-tentacular. It is particularly encouraging to note in his short essay on sanatorium treatment that, at the Yardley Road Sanatorium, the bad old custom of loafing is becoming a lost art, and the pernicious system of monotonous, unremunerated work, masquerading as "graduated, therapeutic labour" is giving place to interesting employment of a productive nature and with an educational value.

Classification of Pulmonary Tuberculosis.

In one of the appendices to Dr. Dixon's report Dr. E. G. Glover, medical superintendent of Salterly Grange Sanatorium, gives some useful hints as to classification of tuberculosis, a subject which has been discussed in papers by Dr. Niven Robertson and Dr. W. B. Knobel in the December number of *Tubercle.* Dr. Glover exposes the frailties of the purely anatomical classification in one illuminating adjective. It is *sartorial.* The classification which he prefers puts sputum negative cases in Group I., the case which changes from sputum positive to sputum negative under primary treatment in Group II., and the case which remains sputum positive during treatment in Group III. His is a good working rule, with purely objective criteria easily rubricised. As the researches of Dr. N. D. Bardswell and many others have shown, the factors on which this classification is founded are of far-reaching prognostic significance. Yet this classification still ignores the three most important influences determining the patient's fate—balance of mind, a balance at the bank, and the sympathy of relatives and employers. The second of these can, of course, be rubricised, but the first and the last are difficult to gauge and tabulate.

The Danger of Tuberculous Milk.

Dr. James C. Gilchrist, honorary secretary of the King Edward VII. Welsh National Memorial Association for the Prevention, Treatment, and Abolition of Tuberculosis, has sent us for publication a resolution passed after discussion by a group of 16 tuberculosis officers and institution superintendents under the Association:—

> That this conference of the medical staff of the Welsh National Memorial Association unanimously affirm as their view that the distribution of milk containing tubercle bacilli is fraught with danger to the lives and health of children consuming it, and that the hypothesis that tubercle bacilli consumed in milk may produce a degree of immunisation is no reason for the abatement of any efforts directed towards producing a tubercle free milk.

A statement drawn up by a prominent U.S. official on the tuberculin test as a factor in the milk traffic has been issued to the press by Mr. Emile Berliner, President of the Washington Tuberculosis Association, and (incidentally) inventor of the gramophone. The tuberculin test as a means for insuring a safe and sanitary milk-supply is described in this statement as wholly inadequate.

> A herd may be tested to-day and no reacting animals be found, and again tested in six months, when one or several animals may be discovered with tuberculosis. It is entirely possible that within a month from the first test the milk

from that herd may contain living, active, virulent tubercle bacilli. And such milk, if consumed in the raw state, in particular by children, may give them tuberculosis, notably of the intestines, of the spine, and of the glands. Butter made from the raw cream of such milk would likewise contain the bacilli in an active and virulent state for at least four to five months. It is comparatively easy to "dope" a herd with certain easily obtainable chemicals and thereby prevent the tuberculin from acting in a test, even though animals in the herd are afflicted with open tuberculosis.

The conclusion is drawn that only proper pasteurisation under official supervision and direction will give to a community a safe milk- and cream-supply.

The Auto-Urine and Serum Tests for Active Tuberculosis.

The reaction which Professor Wildbolz, of Berne,[1] described last year promises to supply a much-needed test for active tuberculosis in an early stage of the disease. It is a safe prophecy that his auto-urine reaction and the auto-serum reaction more recently reported on by his assistant, Dr. Imhof,[2] will figure prominently in the medical journals for some years to come. In passing it may be noted that the principle of auto-sero-diagnosis is not new, and even before the war its possibilities were being discussed. Wildbolz assumes, and gives numerous arguments in support of his assumption, that in active tuberculosis antigens are excreted by the urine and can be demonstrated by intracutaneous inoculation of the producer of the urine or any other tuberculous patient. When a tuberculous lesion is latent no antigens are demonstrable in the urine, and the test is therefore, according to Wildbolz, superior to v. Pirquet's, which indicates infection without clearly distinguishing between latent infection and active disease. It was found that urine had to be condensed by evaporation in vacuo before its antigen content was sufficiently concentrated to provoke an intracutaneous reaction. A negative reaction was obtained when healthy urine was injected into the skin of healthy persons or when the tuberculous were inoculated with the urine of healthy persons. The urine of the tuberculous also failed to give a positive reaction in healthy persons whereas it was nearly always positive when the urine's producer or anyone else gave a positive reaction to a 1 in 1000 solution of tuberculin. There was never a general or focal reaction, only a local reaction. V. Pirquet's and Wildbolz's reactions were strikingly parallel and confirmatory of each other. Dr. Imhof's paper is chiefly concerned with the auto-serum test which he has carried out with blood deproteinised by precipitation with alcohol. He points out that there are various drawbacks to the auto-urine reaction, which is more painful, more apt to provoke necrosis of the skin, and more subject to error on account of variations in the concentration and other properties of the urine than the auto-serum test. In bi-lateral renal tuberculosis, for example, the auto-urine reaction may be negative. Imhof's comparison of the auto-serum with the auto-urine reaction in more than 80 cases showed a close conformity between the two. In 30 cases of surgical tuberculosis both reactions were positive with only one exception. In another group of 34 cases admitted to hospital for accidents or non-tuberculous diseases, both reactions were invariably negative. But perhaps the most instructive of all his cases were those in which the two auto-reactions were at variance with the clinical diagnosis. Among these were nine patients admitted to hospital for accidents or non-tuberculous diseases. All gave a positive reaction to both tests, although there was at the time no clinical evidence of tuberculosis. These cases were, however, watched and no fewer than five subsequently developed signs of pulmonary disease.

Only a few papers have hitherto dealt with control investigations of the claims of the Berne school. Miche[3] does not accept all of them, but Lanz[4] has carried out important investigations, which are confirmatory and which show how various errors may be eliminated. Much of his work concerns the treatment of the urine with a view to removing its most irritating, non-specific elements which obscure the intracutaneous reaction. Gramén,[5] working at the St. Göran's Hospital in Stockholm, seems greatly impressed by the value of the reaction which he has tested in about 50 cases. Obviously it is too early to form a correct opinion of the importance of these reactions, but if the claims already made on their behalf are justified, an advance of very great importance has been made in the early diagnosis of active tuberculosis. The principle concerned may also possibly be extended to the early diagnosis of tuberculosis in cattle, for, as Wildbolz has intimated, tuberculous antigens in the milk of a cow may, perhaps, be demonstrable by an ophthalmo-reaction in the same animal.

A University Sanatorium.

On Dec. 16th Dr. Louis Vauthier recounted before the Geneva Medical Society the story of his scheme for the relief of students stricken with phthisis in the midst of their course of study. During many years at Leysin Dr. Vauthier has been sadly impressed by the large number of patients of this class who come for treatment and by the particularly unfortunate position in which they find themselves. To many the abandonment of their professional studies at a late stage spells the ruin of a career. In all cases the extra anxiety resulting from uncertainty as to their future life's work constitutes a serious moral obstacle to successful therapy. Dr. Vauthier therefore conceived the idea of establishing a university sanatorium where study might be pursued concurrently with a well-ordered course of treatment. His proposals were very warmly received by the senates of the three universities in Romance Switzerland—those of Geneva, Neufchatel, and Lausanne. In July, 1919, representatives of these universities met and constituted a committee of action. The universities of German Switzerland were appealed to and promised their support. In March, 1920, the project was placed before the governing body of the League of Red Cross Societies and received its blessing. Later it was taken up with enthusiasm by the World's Student Christian Federation, the students of Belgium, Holland, France, Spain, and Roumania being particularly active. At the present time a booklet is being prepared which will give a history of the scheme, an outline of the organisation of the proposed institution, and an appeal for the coöperation of foreign universities. The University hopes to draw its students from each of the 31 member nations adhering to the League of Red Cross Societies.

MEDICINE AND THE LAW.

A Medical Witness and Punctuality.

AT a recent inquest in North Leicestershire, at which there were only two witnesses, the mother of a child killed through the upsetting of a pot full of scalding tea, and a medical practitioner, the latter arrived late. On his entering the court the coroner is reported as having said to him: "I don't know whether you are used to inquests, but in my district punctuality must be insisted on." To this the medical man replied that it was difficult for him to leave people who were dying, and that he had been called to another place to attend a patient who had to be sent to a hospital. The coroner was not satisfied and a further discussion took place, the witness protesting that he meant no disrespect, but that a dying man claimed his aid, and the coroner insisting that all witnesses, medical and otherwise, must be punctual at inquests. Finally the coroner said that he did not desire for a moment to impute or suggest intentional discourtesy, but that when a medical man could not get to an inquest in time he should find means of letting him or his officers know. He would then be prepared to hold things over. This probably is the best solution that can be arrived at in circumstances which fortunately do not often occur. None can deny that the coroner is entitled to all respect and to the punctual arrival of witnesses. He could not get through his work otherwise, and in modern times, with telephonic and telegraphic communication, fairly prompt notice of necessary absence or delay can usually be given. There must, however, sometimes, if rarely, be occasions when the choice will lie between keeping the court waiting and leaving a dying person unattended, and when there is no time or when there are no means for informing the coroner or possibly a bench of magistrates. Such a thing might even happen conceivably when a judge was expecting the witness at a court of assize, although then, as a rule, a medical man would have made arrangements with a colleague to attend his patients in cases of urgency. What should be done in such an emergency? There can, it is submitted, hardly be any question that the medical man's duty is to concern himself with the saving of life if he has reasonable cause to believe that life will be imperilled by his not responding to the call for his assistance. He will then have to trust to the courtesy and humanity of the court before which he should have attended, and should go there to make his excuse with the least possible delay. Stress, however, is laid upon the necessity for practical certainty as to the urgency of the need for immediate medical aid, and in the case of a witness bound over to appear in an assize court it is strongly recommended that he should in all cases take steps to render the imagined dilemma impossible.

An Inquest on a Case of Anthrax.

On Dec. 20th an inquest was held at Southwark before Dr. F. J. Waldo, sitting with a jury, upon the body of Frederick Griffiths, aged 59, a leather dresser at the Abbey-street factory, Bermondsey, of Messrs. Bevington and Sons, leather merchants. According to the evidence, deceased had worked during the past two years in a wet department, breaking, unhairing, and flushing goat skins from the infected area of the Cape and East India. Previous to this process the skins were washed in water by other workers. Deceased was last at his work on Friday, Dec. 10th; on the following day he complained of a small boil on his neck, and later the neck became swollen. On the 12th, in the absence of his panel doctor, another practitioner painted the swelling with iodine and prescribed ointment. On the 13th his panel doctor advised his removal to Guy's Hospital, where anthrax was diagnosed. He was there treated with Professor Sclavo's serum and, at the same time, the malignant pustules were excised. A second dose of serum was injected on Dec. 14th; the patient died next day. A foreman fellow-worker said deceased, a healthy vigorous man, had not complained of any illness at all. Basins, cold water, soap, nailbrushes, and towels were provided for the workers. Coloured pictures showing the various stages of local anthrax, with printed directions, were hung up at the factory. He himself had noticed the pictures, but had never read the directions as to the showing of suspicious cases to a doctor. He only knew of two previous cases of anthrax at Messrs. Bevington's, one in February, 1919, and one in August, 1920. Both cases recovered under the serum treatment at Guy's Hospital. Dr. Thomas Rose, divisional surgeon to the police, had made a post-mortem examination of the body and said he found no petechiæ, but a film from the spleen showed numerous characteristic, undoubted bacilli and spores of anthrax. A culture from the subcutaneous tissue and lungs gave growths of the same bacillus. Death was due to heart failure from toxæmia induced by œdema of malignant anthrax. The condition was consistent with infection by means of a nail from Cape goat skins. Disinfection was impracticable since the skins would be destroyed by the process. Dr. Waldo, in summing up, said most cases of anthrax in London occurred in Bermondsey, the centre of the leather and tanning trade. Cleanliness was the best preventive of anthrax and hot water ought at once to be provided in addition to cold at Messrs. Bevington's factory. Workmen should notify the foreman immediately the slightest suspicion of anthrax arose, so that serum might at once be injected by a doctor. Too little thought was given to this disease by workers in skins. Trial of the serum should be made in every case. A verdict of misadventure was recorded, the cause of death being anthrax.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Plague Prevention in France.

A FEW isolated cases of bubonic plague have been recorded in France fairly recently. The disease is diagnosed "Malady No. 9" on the notification forms to the police authorities, according to the French Medical Acts, Feb. 10th, 1903, and Sept. 28th, 1916, and it is that fact which aroused curiosity in the French press some time ago. It was suggested that some unknown exotic disease had been introduced in the country by refugees, and had provisionally been called "Malady No. 9." The appearance of the disease was immediately followed by prophylactic measures, consisting in an active campaign of rat destruction. In order to stimulate the general interest a reward of 25 centimes was given for the body of each dead rat. People who were taking an active part in the destruction of rats complained that during this time fleas were becoming more numerous in their homes. This complaint led to the appreciation of the special danger of contamination by fleas during a campaign for rat destruction unless adequate precautions are taken, for dead rats have to be carried about to be checked by the local authorities who give the rewards. These considerations have dictated more elaborate prophylactic measures, which appear in the general instructions issued this week to practitioners by the Ministry of Health. Doctors are asked to point out the danger of handling dead rats on account of their fleas, and are requested to recommend that paraffin or benzene should be poured over dead rats, which should be burnt or properly buried. Amongst other recommendations are the bacteriological examination of the serous effusion or pus contained in glands in order to try to identify Yersin's bacillus in suspicious cases, and the isolation of diagnosed cases and suspicious patients, and their immediate notification to the local authorities. Practitioners are also advised to inject intravenously 100 to 120 c.cm. of the antiplague serum made at the Pasteur Institute, as soon as the disease is diagnosed. It is also suggested that 60 to 80 c.cm. of serum should be injected daily during the next three days. Doctors are furthermore asked to do their best to convince those approaching their patients (nurses, relatives, &c.) of the necessity of being vaccinated. It is specified that vaccination for an adult should consist in a 2 c.cm. subcutaneous injection of the antiplague vaccine made at the Pasteur Institute (½ c.cm. for an infant, 1 c.cm. for a child between 2 and 10). The study of the recent cases of bubonic plague has led to new researches dealing with the bacteriological diagnosis of the disease. Mons. H. Violle, in a communication to the Société de Biologie on the diagnosis of bubonic plague, recommends that when direct examination of serous effusion or pus from a gland has not revealed Yersin's bacillus, a sero-diagnosis should be made not with the blood serum but with fluid or even pus obtained by puncture of a gland. Mons. Violle has observed that with this technique the agglutination can become positive very soon after the onset of the disease. He remarks that this fact is well worth considering since antibodies appear only much later in the blood.

Encephalitis Lethargica and Hiccup.

In a recent article in the *Presse Médicale* Mons. J. Lhermitte refers to cases of persistent hiccup with nasal and bronchial catarrh, malaise, and slight fever, which have recently occurred in France and elsewhere in Europe. Other cases have occurred concurrently with an epidemic of encephalitis lethargica and since the usual symptoms of this latter disease have in some cases been preceded by persistent hiccup with nasal and bronchial catarrh, malaise, and slight fever, he concludes that the syndrome represents a disease of a similar nature. This opinion has already been expressed at the Société Médicale des Hôpitaux by MM. Netter, W. Dufour, and R. Bénard, and lately at the Société de Neurologie by MM. J. Sicard and J. Paraf.

Dec. 25th, 1920.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Prize-giving at the Royal College of Surgeons in Ireland.

THE annual distribution of prizes in the school of the Royal College of Surgeons in Ireland took place on Dec. 18th, when an address to the students was delivered by the Vice-President, Sir W. I. de C. Wheeler, in the absence, due to illness, of the President. The Vice-President contrasted the present conditions of medical study with those found when he was a student. At that time the operating theatre still savoured of the bull-ring, and anæsthesia was in its infancy. The physician's top hat and double-breasted coat had now disappeared, and the possession of a pure water-supply had done more for the cause of temperance than a thousand Pussyfoot campaigns. The College, the only unendowed school of medicine in Ireland, had strong claims for State aid, which had not yet been met. On the medical side of practice the belief in drugs still held too much sway, while surgery was as yet saturated with reaction and conservatism. He advised his hearers to keep their minds open and independent. They should work with each other as comrades, not as competitors.

Resignation of Professor Hugh A. Auchinleck.

Professor H. A. Auchinleck, who has been professor of medical jurisprudence in the school of the Royal College of Surgeons for more than a generation, has now resigned that post and retired from practice. The students of the school entertained him to dinner last week prior to his leaving Dublin for a visit to East Africa. The Vice-President occupied the chair and several of his colleagues were also the guests of the students.

The Use of the Red Cross by Doctors.

Sir John Lumsden, chairman of the Joint Committee in Ireland of the St. John Ambulance Association and the British Red Cross Society, has, with the consent of his London headquarters, advised medical practitioners in Ireland to affix a Red Cross badge in a prominent position on their motor-cars so as to be visible by day or night, in order to protect from shooting should the occupant fail to hear a challenge.

Death of Dr. George Peacocke.

The death of Dr. George Peacocke, of Dublin, occurred on Christmas morning after a few days' illness. He was struck down by pneumonia very suddenly, and few of his friends had heard of his illness until the news of his death became public. Dr. Peacocke was still a young man, not much over 50, and was always of robust health. He was educated in Trinity College, Dublin, taking his medical degrees in 1892. His whole professional career was associated with the Adelaide Hospital, where he was successively house physician, assistant physician, and physician. He took much interest in the affairs of the Royal College of Physicians, and held for a time the offices of censor and vice-president. He was, since its foundation, chairman of the Irish branch of the College of Nursing, Ltd. He had also been president of the Section of Medicine of the Royal Academy of Medicine in Ireland, and contributed frequently to its Transactions and to the medical journals. As a capable and thoughtful physician and an upright man he was held in much respect in Dublin, and will be greatly missed by his professional brethren.

Ulster Medical Society.

Dr. Thomas Houston, the president of the Society, and Miss Houston gave an "At Home" to members and their friends, at the Medical Institute, Belfast, on the evening of Dec. 18th, 1920, when Major J. A. Sinton, V.C., was presented with the certificate of Honorary Fellowship of the Society. The certificate is in the form of a tryptich bound in Russia leather and is ornamented by water-colour drawings of Queen's University, the Royal Victoria Hospital, and the Medical Institute, with reproductions of the Victoria Cross and the Russian Order of St. George, and the crests of the Indian Medical Service and the Ulster Medical Society. It reads as follows:—

> "This is to certify that John Alexander Sinton, V.C., M.D., D.P.H., Indian Medical Service, has been elected an Honorary Fellow of the Ulster Medical Society in appreciation of the conspicuous gallantry and devotion to duty which have earned for him the greatest distinction which a British soldier can obtain—the Victoria Cross for Valour."

Dec. 28th.

URBAN VITAL STATISTICS.

(Week ended Dec. 18th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 13·5, 13·2, and 12·9 in the three preceding weeks, rose to 15·3 per 1000. In London, with a population of nearly 4½ million persons, the death-rate was 16·0, or 3·1 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 7·1 in Ealing, 7·2 in Gillingham, and 7·4 in Walthamstow, to 21·4 in Bath, 21·6 in Tynemouth, and 21·8 in Merthyr Tydfil. The principal epidemic diseases caused 247 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 93 from infantile diarrhœa, 76 from diphtheria, 33 from measles, 26 from whooping-cough, 16 from scarlet fever, and 3 from enteric fever. Measles caused a death-rate of 1·2 in Sheffield and in Middlesbrough, 1·4 in Smethwick and in Barrow-in-Furness, and 1·7 in Walsall. There were 4994 cases of scarlet fever and 2654 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 5297 and 2654 respectively at the end of the previous week. The causes of 40 of the 5217 deaths in the 96 towns were uncertified, of which 10 were registered in Birmingham, 5 in London, and 3 each in Liverpool and Rhondda.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 14·3, 13·5, and 15·2 in the three preceding weeks, rose to 16·1 per 1000. The 363 deaths in Glasgow corresponded to an annual rate of 17·0 per 1000, and included 7 from infantile diarrhœa, and 5 each from whooping-cough and diphtheria. The 92 deaths in Edinburgh were equal to a rate of 14·1 per 1000. and included 2 from infantile diarrhœa and 1 from diphtheria.

Irish Towns.—The 161 deaths in Dublin corresponded to an annual rate of 20·2, or 2·1 per 1000 above that recorded in the previous week, and included 7 from infantile diarrhœa, 4 from whooping-cough, and 1 each from scarlet fever and diphtheria. The 126 deaths in Belfast were equal to a rate of 15·9 per 1000, and included 2 each from scarlet fever and infantile diarrhœa, and 1 from diphtheria.

The Services.

ARMY MEDICAL SERVICE.

Temp. Major-Gen. Sir R. Jones, (Major, R.A.M.C., T.F.) relinquishes his temporary commission.

ROYAL ARMY MEDICAL CORPS.

R. Fitz-J. Haythornthwaite to be temporary Lieutenant.

Officers relinquishing their commissions: Temp. Lieut.-Col. W. J. N. Vincent, on ceasing to be employed at the Wharncliffe War Hospital (retains the rank of Lieutenant-Colonel). Temp. Major J. Dalrymple (granted the rank of Lieutenant-Colonel). Temp. Capt. A. G. Welsford (granted the rank of Major).

SPECIAL RESERVE OF OFFICERS.

Capt. E. S. Mawe relinquishes his commission on account of ill-health contracted on active service and retains the rank of Captain.

TERRITORIAL FORCE.

Capt. C. E. K. Herapath to be Major.

Temp. Major W. A. Smith (4th Bn., East Lancs. Regt. relinquishes his temporary commission.

Capts. A. C. Court (late R.A.M.C., S.R.) and A. G. M. Middleton (late R.A.M.C.) to be Captains.

Supernumerary for service with O.T.C.:—Lieut. D. R. Wheeler (late R.A.M.C.) to be Lieutenant for service with Belfast University Contingent, Senior Division, Officers Training Corps. London University Contingent: Capt. J. H. Ryffel resigns his commission and retains the rank of Captain.

INDIAN MEDICAL SERVICE

Lieut.-Col. R. Steen is transferred to the temporary non-effective list.

The King has approved the admission of the undermentioned to the I.M.S.:—To be Captains: Major W. J. Webster (late R.A.M.C., S.R.); Capt. G. M. Moffatt (late 3rd Bn., R. Dub. Fus., S.R.), Capt. J. M. Mitchell (late R.A.M.C.).

necessary absence or delay can usually be given. There must, however, sometimes, if rarely, be occasions when the choice will lie between keeping the court waiting and leaving a dying person unattended, and when there is no time or when there are no means for informing the coroner or possibly a bench of magistrates. Such a thing might even happen conceivably when a judge was expecting the witness at a court of assize, although then, as a rule, a medical man would have made arrangements with a colleague to attend his patients in cases of urgency. What should be done in such an emergency? There can, it is submitted, hardly be any question that the medical man's duty is to concern himself with the saving of life if he has reasonable cause to believe that life will be imperilled by his not responding to the call for his assistance. He will then have to trust to the courtesy and humanity of the court before which he should have attended, and should go there to make his excuse with the least possible delay. Stress, however, is laid upon the necessity for practical certainty as to the urgency of the need for immediate medical aid, and in the case of a witness bound over to appear in an assize court it is strongly recommended that he should in all cases take steps to render the imagined dilemma impossible.

An Inquest on a Case of Anthrax.

On Dec. 20th an inquest was held at Southwark before Dr. F. J. Waldo, sitting with a jury, upon the body of Frederick Griffiths, aged 59, a leather dresser at the Abbey-street factory, Bermondsey, of Messrs. Bevington and Sons, leather merchants. According to the evidence, deceased had worked during the past two years in a wet department, breaking, unhairing, and flushing goat skins from the infected area of the Cape and East India. Previous to this process the skins were washed in water by other workers. Deceased was last at his work on Friday, Dec. 10th; on the following day he complained of a small boil on his neck, and later the neck became swollen. On the 12th, in the absence of his panel doctor, another practitioner painted the swelling with iodine and prescribed ointment. On the 13th his panel doctor advised his removal to Guy's Hospital, where anthrax was diagnosed. He was there treated with Professor Sclavo's serum and, at the same time, the malignant pustules were excised. A second dose of serum was injected on Dec. 14th; the patient died next day. A foreman fellow-worker said deceased, a healthy vigorous man, had not complained of any illness at all. Basins, cold water, soap, nailbrushes, and towels were provided for the workers. Coloured pictures showing the various stages of local anthrax, with printed directions, were hung up at the factory. He himself had noticed the pictures, but had never read the directions as to the showing of suspicious cases to a doctor. He only knew of two previous cases of anthrax at Messrs. Bevington's, one in February, 1919, and one in August, 1920. Both cases recovered under the serum treatment at Guy's Hospital. Dr. Thomas Rose, divisional surgeon to the police, had made a post-mortem examination of the body and said he found no petechiæ, but a film from the spleen showed numerous characteristic, undoubted bacilli and spores of anthrax. A culture from the subcutaneous tissue and lungs gave growths of the same bacillus. Death was due to heart failure from toxæmia induced by œdema of malignant anthrax. The condition was consistent with infection by means of a nail from Cape goat skins. Disinfection was impracticable since the skins would be destroyed by the process. Dr. Waldo, in summing up, said most cases of anthrax in London occurred in Bermondsey, the centre of the leather and tanning trade. Cleanliness was the best preventive of anthrax and hot water ought at once to be provided in addition to cold at Messrs. Bevington's factory. Workmen should notify the foreman immediately the slightest suspicion of anthrax arose, so that serum might at once be injected by a doctor. Too little thought was given to this disease by workers in skins. Trial of the serum should be made in every case. A verdict of misadventure was recorded, the cause of death being anthrax.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Plague Prevention in France.

A FEW isolated cases of bubonic plague have been recorded in France fairly recently. The disease is diagnosed "Malady No. 9" on the notification forms to the police authorities, according to the French Medical Acts, Feb. 10th, 1903, and Sept. 28th, 1916, and it is that fact which aroused curiosity in the French press some time ago. It was suggested that some unknown exotic disease had been introduced in the country by refugees, and had provisionally been called "Malady No. 9." The appearance of the disease was immediately followed by prophylactic measures, consisting in an active campaign of rat destruction. In order to stimulate the general interest a reward of 25 centimes was given for the body of each dead rat. People who were taking an active part in the destruction of rats complained that during this time fleas were becoming more numerous in their homes. This complaint led to the appreciation of the special danger of contamination by fleas during a campaign for rat destruction unless adequate precautions are taken, for dead rats have to be carried about to be checked by the local authorities who give the rewards. These considerations have dictated more elaborate prophylactic measures, which appear in the general instructions issued this week to practitioners by the Ministry of Health. Doctors are asked to point out the danger of handling dead rats on account of their fleas, and are requested to recommend that paraffin or benzene should be poured over dead rats, which should be burnt or properly buried. Amongst other recommendations are the bacteriological examination of the serous effusion or pus contained in glands in order to try to identify Yersin's bacillus in suspicious cases, and the isolation of diagnosed cases and suspicious patients, and their immediate notification to the local authorities. Practitioners are also advised to inject intravenously 100 to 120 c.cm. of the antiplague serum made at the Pasteur Institute, as soon as the disease is diagnosed. It is also suggested that 60 to 80 c.cm. of serum should be injected daily during the next three days. Doctors are furthermore asked to do their best to convince those approaching their patients (nurses, relatives, &c.) of the necessity of being vaccinated. It is specified that vaccination for an adult should consist in a 2 c.cm. subcutaneous injection of the antiplague vaccine made at the Pasteur Institute (½ c.cm. for an infant, 1 c.cm. for a child between 2 and 10). The study of the recent cases of bubonic plague has led to new researches dealing with the bacteriological diagnosis of the disease. Mons. H. Violle, in a communication to the Société de Biologie on the diagnosis of bubonic plague, recommends that when direct examination of serous effusion or pus from a gland has not revealed Yersin's bacillus, a sero-diagnosis should be made not with the blood serum but with fluid or even pus obtained by puncture of a gland. Mons. Violle has observed that with this technique the agglutination can become positive very soon after the onset of the disease. He remarks that this fact is well worth considering since antibodies appear only much later in the blood.

Encephalitis Lethargica and Hiccup.

In a recent article in the *Presse Médicale* Mons. J. Lhermitte refers to cases of persistent hiccup with nasal and bronchial catarrh, malaise, and slight fever, which have recently occurred in France and elsewhere in Europe. Other cases have occurred concurrently with an epidemic of encephalitis lethargica and since the usual symptoms of this latter disease have in some cases been preceded by persistent hiccup with nasal and bronchial catarrh, malaise, and slight fever, he concludes that the syndrome represents a disease of a similar nature. This opinion has already been expressed at the Société Médicale des Hôpitaux by MM. Netter, W. Dufour, and R. Bénard, and lately at the Société de Neurologie by MM. J. Sicard and J. Paraf.

Dec. 25th, 1920.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Prize-giving at the Royal College of Surgeons in Ireland.

THE annual distribution of prizes in the school of the Royal College of Surgeons in Ireland took place on Dec. 18th, when an address to the students was delivered by the Vice-President, Sir W. I. de C. Wheeler, in the absence, due to illness, of the President. The Vice-President contrasted the present conditions of medical study with those found when he was a student. At that time the operating theatre still savoured of the bull-ring, and anæsthesia was in its infancy. The physician's top hat and double-breasted coat had now disappeared, and the possession of a pure water-supply had done more for the cause of temperance than a thousand Pussyfoot campaigns. The College, the only unendowed school of medicine in Ireland, had strong claims for State aid, which had not yet been met. On the medical side of practice the belief in drugs still held too much sway, while surgery was as yet saturated with reaction and conservatism. He advised his hearers to keep their minds open and independent. They should work with each other as comrades, not as competitors.

Resignation of Professor Hugh A. Auchinleck.

Professor H. A. Auchinleck, who has been professor of medical jurisprudence in the school of the Royal College of Surgeons for more than a generation, has now resigned that post and retired from practice. The students of the school entertained him to dinner last week prior to his leaving Dublin for a visit to East Africa. The Vice-President occupied the chair and several of his colleagues were also the guests of the students.

The Use of the Red Cross by Doctors.

Sir John Lumsden, chairman of the Joint Committee in Ireland of the St. John Ambulance Association and the British Red Cross Society, has, with the consent of his London headquarters, advised medical practitioners in Ireland to affix a Red Cross badge in a prominent position on their motor-cars so as to be visible by day or night, in order to protect from shooting should the occupant fail to hear a challenge.

Death of Dr. George Peacocke.

The death of Dr. George Peacocke, of Dublin, occurred on Christmas morning after a few days' illness. He was struck down by pneumonia very suddenly, and few of his friends had heard of his illness until the news of his death became public. Dr. Peacocke was still a young man, not much over 50, and was always of robust health. He was educated in Trinity College, Dublin, taking his medical degrees in 1892. His whole professional career was associated with the Adelaide Hospital, where he was successively house physician, assistant physician, and physician. He took much interest in the affairs of the Royal College of Physicians, and held for a time the offices of censor and vice-president. He was, since its foundation, chairman of the Irish branch of the College of Nursing, Ltd. He had also been president of the Section of Medicine of the Royal Academy of Medicine in Ireland, and contributed frequently to its Transactions and to the medical journals. As a capable and thoughtful physician and an upright man he was held in much respect in Dublin, and will be greatly missed by his professional brethren.

Ulster Medical Society.

Dr. Thomas Houston, the president of the Society, and Miss Houston gave an "At Home" to members and their friends, at the Medical Institute, Belfast, on the evening of Dec. 18th, 1920, when Major J. A. Sinton, V.C., was presented with the certificate of Honorary Fellowship of the Society. The certificate is in the form of a tryptich bound in Russia leather and is ornamented by water-colour drawings of Queen's University, the Royal Victoria Hospital, and the Medical Institute, with reproductions of the Victoria Cross and the Russian Order of St. George, and the crests of the Indian Medical Service and the Ulster Medical Society. It reads as follows:—

> "This is to certify that John Alexander Sinton, V.C., M.D., D.P.H., Indian Medical Service, has been elected an Honorary Fellow of the Ulster Medical Society in appreciation of the conspicuous gallantry and devotion to duty which have earned for him the greatest distinction which a British soldier can obtain—the Victoria Cross for Valour."

Dec. 28th.

URBAN VITAL STATISTICS.

(Week ended Dec. 18th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 13·5, 13·2, and 12·9 in the three preceding weeks, rose to 15·3 per 1000. In London, with a population of nearly 4½ million persons, the death-rate was 16·0, or 3·1 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 7·1 in Ealing, 7·2 in Gillingham, and 7·4 in Walthamstow, to 21·4 in Bath, 21·6 in Tynemouth, and 21·8 in Merthyr Tydfil. The principal epidemic diseases caused 247 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 93 from infantile diarrhœa, 76 from diphtheria, 33 from measles, 26 from whooping-cough, 16 from scarlet fever, and 3 from enteric fever. Measles caused a death-rate of 1·2 in Sheffield and in Middlesbrough, 1·4 in Smethwick and in Barrow-in-Furness, and 1·7 in Walsall. There were 4994 cases of scarlet fever and 2654 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 5297 and 2654 respectively at the end of the previous week. The causes of 40 of the 5217 deaths in the 96 towns were uncertified, of which 10 were registered in Birmingham, 5 in London, and 3 each in Liverpool and Rhondda.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had been 14·3, 13·5, and 15·2 in the three preceding weeks, rose to 16·1 per 1000. The 363 deaths in Glasgow corresponded to an annual rate of 17·0 per 1000, and included 7 from infantile diarrhœa, and 5 each from whooping-cough and diphtheria. The 92 deaths in Edinburgh were equal to a rate of 14·1 per 1000, and included 2 from infantile diarrhœa and 1 from diphtheria.

Irish Towns.—The 161 deaths in Dublin corresponded to an annual rate of 20·2, or 2·1 per 1000 above that recorded in the previous week, and included 7 from infantile diarrhœa, 4 from whooping-cough, and 1 each from scarlet fever and diphtheria. The 126 deaths in Belfast were equal to a rate of 15·9 per 1000, and included 2 each from scarlet fever and infantile diarrhœa, and 1 from diphtheria.

The Services.

ARMY MEDICAL SERVICE.

Temp. Major-Gen. Sir R. Jones, (Major, R.A.M.C., T.F.) relinquishes his temporary commission.

ROYAL ARMY MEDICAL CORPS.

R. Fitz-J. Haythornthwaite to be temporary Lieutenant.

Officers relinquishing their commissions: Temp. Lieut.-Col. W. J. N. Vincent, on ceasing to be employed at the Wharncliffe War Hospital (retains the rank of Lieutenant-Colonel). Temp. Major J. Dalrymple (granted the rank of Lieutenant-Colonel). Temp. Capt. A. G. Welsford (granted the rank of Major).

SPECIAL RESERVE OF OFFICERS.

Capt. E. S. Mawe relinquishes his commission on account of ill-health contracted on active service and retains the rank of Captain.

TERRITORIAL FORCE.

Capt. C. E. K. Herapath to be Major.

Temp. Major W. A. Smith (4th Bn., East Lancs. Regt. relinquishes his temporary commission.

Capts. A. C. Court (late R.A.M.C., S.R.) and A. G. M. Middleton (late R.A.M.C.) to be Captains.

Supernumerary for service with O.T.C.:—Lieut. D. R. Wheeler (late R.A.M.C.) to be Lieutenant for service with Belfast University Contingent, Senior Division, Officers Training Corps. London University Contingent: Capt. J. H. Ryffel resigns his commission and retains the rank of Captain.

INDIAN MEDICAL SERVICE.

Lieut.-Col. R. Steen is transferred to the temporary non-effective list.

The King has approved the admission of the undermentioned to the I.M.S.:—To be Captains: Major W. J. Webster (late R.A.M.C., S.R.); Capt. G. M. Moffatt (late 3rd Bn., R. Dub. Fus., S.R.), Capt. J. M. Mitchell (late R.A.M.C.).

THE HORSLEY MEMORIAL.

THE executive committee of the Horsley Memorial has now published the first list of subscriptions towards the foundation of a lectureship or scholarship in order to commemorate the services of the late Sir Victor Horsley to science and to the Empire. The absence of numbers of medical men on war service prevented the taking of steps in this matter until a short while ago, but the memory of Sir Victor Horsley's tragic death in Mesopotamia is still fresh, and will be brought back acutely to all minds by the announcement of the death on Christmas Day of his elder and only surviving son. It is certainly not too late to move for the recognition in a permanent form of Horsley's life and work. It is suggested that the most appropriate trustees would be the Senate of the University of London, and that if a lectureship be finally decided upon the subject should be left widely open, in order to secure the services of men distinguished in various departments of public life to deliver the yearly Victor Horsley Lecture.

Sir Victor Horsley was one of the most noteworthy students of University College Hospital, a distinguished medallist and graduate of the University of London, a leader and first chairman of the Representative Meeting of the British Medical Association, and a Fellow of the Royal Society. His pioneer research work connected with surgery of the brain and nervous system and the causation of myxœdema, and his investigations as secretary of the commission appointed to inquire into the value of Pasteur's treatment of rabies, were amongst his great achievements; but his distinction in science and surgery was the result of only a part of his labours. He was possessed of a great desire for the improvement of the social conditions of his country, and so found himself a leader of various more or less unpopular causes, which he upheld with a fervour not always devoid of offence to his opponents; his devotion to reforms connected with temperance, to the enfranchisement of women, the welfare of children, and the abolition of slums, will long be remembered; and he has left behind him the memory of a brilliant and painstaking teacher and a great and honourable public servant.

The first list of subscriptions, paid and promised, is as follows:—

	£	s.	d.
Sir Frederick Mott, K.B.E., and Lady Mott, Dr. Camac Wilkinson, Sir George Newman, K.C.B., Dr. J. O. Wakelin Barratt, Dr. and Mrs. George Murray ... each	10	10	0
Rt. Hon. Lord Edmond Fitzmaurice, Sir Felix Semon, K.C.V.O., Dr. Mary Sturge, Dr. Slinger, C. J. Bond, C.M.G., Dr. Farquhar Buzzard, Right Hon. Leif Jones, Percy Sargent, C.M.G., D.S.O. ... ... each	10	0	0
Sir W. Arbuthnot Lane, Bart., Sir G. Sims Woodhead, K.B.E., N. Bishop Harman, Dr. H. H. Tooth, C.B., C.M.G., Dr. Otto May, Dr. A. Salusbury McNalty, Ewen J. Maclean, Edward J. Domville, O.B.E., S. H. Burton, J. Smith Whitaker, Sir John Bland-Sutton, Dr. Blacker, C.B.E., Lieut.-Col. R. McCarrison, Mrs. McCarrison, H. Huxley, Raymond Johnson, O.B.E., Dr. Gordon Holmes, C.M.G., C.B.E., Sir Hamilton Ballance, K.B.E., C.B., Dr. W. H. Willcox, C.B., C.M.G., Society of Members of the Royal College of Surgeons, Professor E. H. Starling, F.R.S.... ... ... each	5	5	0
Right Hon. Sir T. Clifford Allbutt, K.C.B., Sir Charles Ballance, K.C.M.G., Dr. A. Fulton, Sir J. Rose Bradford, K.C.M.G., C.B., C.B.E., Right Hon. T. R. Ferens, Dr. Frank Hinds, W. G. Spencer, O.B.E.... ... ... each	5	0	0
Mr. and Mrs. Stephen Paget, Sir Rickman J. Godlee, Bart., K.C.V.O. ... ... each	3	3	0
Dr. R. A. Bolam, O.B.E., Dr. T. Ridley Bailey, Sir T. Jenner Verrall, LL.D., Dr. Dawson Williams, Dr. R. H. Clarke, Dr. Percy Rose, Dr. Steen, Dr. Lauriston Shaw, Dr. E. W. Goodall, O.B.E., Dr. Alfred Cox, O.B.E., Dr. Rigden, Lady Barrett, C.B.E., Col. Sir A. W. Mayo-Robson, K.B.E., C.B., C.V.O., Sir Leonard Rogers, C.I.E., Sir Hugh Beevor, Dr. Squire Sprigge ... ... each	2	2	0
Dr. C. E. S. Flemming, Dr. Garstang, Dr. Hawthorne, Sir Charles Harrison, Dr. O'Sullivan, Dr. Henry Sturge, Col. Mansell Moullin, C.B.E., Professor Rutherford Morison, Dr. Eleanor Lowry, Dr. Russell Wells, Anonymous ... ... each	1	1	0
Miss Powning, Dr. Henry Bird, Dr. J. J. Muskens... each	1	0	0

The hon. treasurers of the Memorial are Sir Frederick Mott, K.B.E., F.R.S., 25, Nottingham-place, W.1, and Dr. H. H. Tooth, C.B., C.M.G., 34, Harley-street, W.1; the hon. ecretaries are Sir W. Arbuthnot Lane, Bart., 21, Cavendish-quare, W.1, and Edward J. Domville, Esq., C.B.E., Symonds-ry, Bridport. Subscriptions may be paid to either of the named, or to the "Victor Horsley Memorial Account," den County Westminster and Parr's Bank, Hanover-re Branch.

Correspondence.

"Audi alteram partem."

THE FUTURE OF POOR-LAW INFIRMARIES.

To the Editor of THE LANCET.

SIR,—The statements made by different eminent speakers at a meeting of the Harveian Society, of which you give a full account in your issue of Dec. 25th, are such as to cause just indignation among all connected professionally with Poor-law hospitals or infirmaries. They make one wonder also whether the speakers do in fact know anything about the ordinary modern Poor-law hospital. We learn that "sick people have been provided in the past with little else than food and shelter"; and the speaker is not, from the context, referring to at all a remote past. We are told that there is no provision for obtaining Wassermann tests, bismuth X ray pictures, blood cultures or counts, or X ray examinations for tubercle. It is suggested kindly that one general practitioner may be equal to three "medical State officials," which in this connexion can only mean the resident medical staff of the infirmaries; this to men who see daily the disastrous effects of delay and inadequate treatment at home and at out-patient departments. It appears that our general equipment is poor and our laboratory equipment nil, and that we treat only incurable and chronic cases. These are some of the statements, in their own words, of speakers who contemplate absorbing the Poor-law hospitals into the voluntary system.

Now no thoughtful man in a position to judge can deny, or wishes to deny, that great changes and improvements are necessary in Poor-law hospitals both for present purposes and if they are to take on a larger section of the public as their patients. And no medical superintendent who has borne for years the burden of responsibility for clinical and administrative work together can fail to see that, whatever be the effect on his own position, a wide expansion of medical staff must result from the new conditions. Already there are few infirmaries which have not specialists attached, either visiting regularly or available when desired, and this is an arrangement advocated for many years by the Medical Superintendents' Society and due entirely to the initiative of individual superintendents. And unquestionably if these hospitals, under the name of municipal hospitals or otherwise, are to be used by the main body of middle- and working-class patients, public opinion will legitimately demand that they shall have a numerous professional staff of the highest possible qualifications. For though specialism is possibly somewhat overdone and a smaller number of patients than is generally supposed suffer through lack of "specialist" advice, nevertheless it is wrong that any risk should be run of even a small number of patients so suffering. That there is this risk at present cannot be denied.

But, Sir, in what spirit is this "linking-up" process to be approached? Is is to be mere swallowing up by the voluntary system, itself by no means free from reproach? Or is it to be a genuine and reciprocal coöperation? Or is it to be avowed rivalry—pull voluntary, pull municipal, and the devil take the hindmost? And is it certain that in 20 years time the municipal hospital would be that hindmost? If those responsible for the policy of the voluntary hospitals begin by throwing out grotesque mis-statements of this sort, how do they expect to be welcomed? We do not pretend to be other than we are. We are not teaching schools and cannot pretend to the skill or repute of the acknowledged leaders of the profession, the picked men, to be found in them. But such as we are we have fought our fight for improvement year after year, with no help from the voluntary hospitals as such, though with generous help often from individuals. The charge cannot with justice be brought against the Poor-law hospitals that they have failed to treat adequately the patients with whom they have had to deal. As the class of patient has altered so gradually the equipment, methods, and staff have expanded, and these hospitals have cured enormous numbers of patients whom the voluntary hospitals have either rejected entirely, or have been obliged, through pressure on their beds, to discharge after quite inadequate periods of treatment.

And now at last the prospect of a great future opens before our Poor-law hospitals. Now, too, the voluntary hospitals begin to take notice of us and to desire to link our future with theirs. But if the attitude of the speakers at the Harveian Society is representative, it may incline us to seek that future independently rather than "link up" with those who regard us as backwaters of stagnancy and neglect. It does not seem by any means certain as yet that the future municipal hospital, if that is to be its name, will be part of the voluntary system. In some ways the tendency seems otherwise. This may be regrettable, but our regret would be a good deal lessened by such statements or mis-statements as these, which, it is well to say plainly, are simply untrue.

Although I feel this protest to be necessary one would rather look at and welcome the manifest desire of every speaker that every available hospital should be put on the highest possible footing. Here we are all on common ground.

One aspect of the matter is too often overlooked. What is to become of the very poor patient and the patient suffering from unattractive disease of a septic nature and the wasting babies rejected by the children's hospitals. At present they "squall" near the "grave case" of one speaker—or perhaps they do not always. At any rate the very poor and those whose illnesses are unattractive, no good for teaching, not creditable to the surgeon, have been squeezed out of the voluntary hospitals, and bid fair to be squeezed out of the Poor-law hospitals too. They will still need treatment, however, and unless that is grasped there is a danger of much hardship resulting. No doubt there are some unused Poor-law infirmary beds, but the number is nothing like so great as has been represented, and the needs of this class should be recognised as well as the needs, urgent indeed as all admit, of those a little above them in the social scale or more obviously and rapidly curable.—I am, Sir, yours faithfully,

J. C. Muir,
Medical Superintendent of the Whipps Cross
Hospital of the West Ham Board
of Guardians.
Dec. 27th, 1920.

CRIMINOLOGY.

To the Editor of The Lancet.

Sir,—The leading article in your issue of Dec. 25th (p. 1314) on the treatment of criminals incites me to suggest what has been for some time in my mind, that some one or more of the bodies who grant a D.P.H. might allow criminology as one of the subjects in its course. I confess that I am thinking of Birmingham, where unusual facilities exist, and teachers who have made it a special study could be found. It might perhaps become a nursery for medical men who wished to enter the prison service.—I am, Sir, yours faithfully,

Dec. 28th, 1920. W. P. Herringham.

SYNOPSIS OF PHYSIOLOGY.

To the Editor of The Lancet.

Sir,—In the notice of my book which appears in The Lancet of Dec. 25th (p. 1311) your reviewer takes exception to the following remark of mine: "Hunger pains ...... are due, as Cannon has shown, to periodic contractions of the stomach wall." He implies that I am incorrect in attributing this discovery to Cannon and that it should properly belong to Carlson. The facts are these: Cannon made the suggestion in a communication to the Boston Society of Medical Science on Jan. 17th, 1911.[1] In collaboration with Washburn he proved it by direct experiment, an account of which appears in the *American Journal of Physiology*, vol. xxix., p. 436, under date March 1st, 1912. The first paper by Carlson on the subject appeared on Dec. 2nd, 1912. Carlson, referring to his own experiments, wrote: "The individual contractions of the group rhythm and the stronger contractions of the continuous rhythm are recognised as hunger pains (confirmation of Cannon and Washburn)."[2] And later, on Jan. 1st, 1913, he wrote: "We owe the actual demonstration of the synchrony of the hunger sensations with the strong contractions of the empty stomach to Cannon and Washburn."[3] Carlson therefore, on his own admission, did but confirm the discovery.

Your reviewer further says: "The central nervous system and reflex action together take up only 16 pages." He makes no mention of the fact that in my book I have arranged the nervous system on a new plan in such a manner that the description of the special senses is woven into the description of the central nervous system. The central nervous system is described in its different aspects on pp. 264–280, 285, 286, 298, 299, 306, 307, 309–317, 321–326. This makes about 35 pages, not 16 as your reviewer states.

I am, Sir, yours faithfully,
Ffrangcon Roberts, M.D., M.R.C.P.
Clare College, Cambridge, Dec. 27th, 1920.

THE ORGANISATION OF THE MEDICAL PROFESSION.

To the Editor of The Lancet.

Sir,—Will you allow me to draw attention to the present position in the organisation of medicine? Excluding for the moment the Royal Colleges, there are three organisations in the medical profession interested in what may be called, for want of a better term, medical politics, namely:—

The British Medical Association, an organisation of individual medical men with a membership of some 20,000 (including those resident in the colonies and abroad), or roughly 52 per cent. of registered practitioners.

The Federation of Medical and Allied Societies, an organisation of societies at present uniting rather more than 18,000 medical practitioners in Great Britain, and some 90,000 of those in the allied dental, pharmaceutical, nursing, and midwives professions.

The Medico-Political Union, an organisation of individual medical practitioners on trade-union lines with a membership of some 3200.

The first and third of these exist to further the interests of doctors alone. The Federation exists to advance the interests of the general public by providing the means of sounding the collective opinion of the various sections in the medical profession, in the allied professions, and in the community at large. As such it neither aspires to leadership nor to control of its constituent bodies.

The view of the Minister of Health may be drawn from his recent statements. On Nov. 1st, 1920, he told a deputation of the B.M.A. that "he was not going to consult half a dozen different bodies each claiming to represent the profession." He also said, "if you want us to consult you, get busy, and set up some machinery whereby you can readily be consulted." He pointed out that "in each area there might be a branch of the B.M.A., but there were also other associations and societies as well." On Dec. 9th, 1920, Dr. Addison received a deputation from the Medico-Political Union, and took the opportunity to make the following remarks:—

> "Since the early days of the Ministry of Health there have been a large number of Deputations of medical men on important subjects which the department has under consideration. In such circumstances the voice of a united medical profession, speaking not of its own interests primarily, is most urgently required, but has not yet been obtained. There is no lack of those who say they represent the profession as a whole, but there is no one body which even claims to represent all interested organisations, though some aspire to. If you wish to procure attention for your views you must agree together first. In no other way is it possible for your views to be completely represented in the councils of those concerned with the reconstruction of our public health system."

The view of the British Medical Association may be gathered from the words of the Medical Secretary and others speaking presumably for the whole body. I may quote the following: "the Association is recognised as the mouthpiece of the profession"; "there is only one organisation in the medical profession—namely, the Association"; "the Association could, if loyally supported by the whole profession, do all that the Federation aims at doing." On Dec. 15th, 1920, the Central Council of the Association rejected the recommendation of the Ministry of Health Subcommittee, which body advised coöperation with the Federation.

[1] See Cannon, The Mechanical Factors of Digestion, 1911, p. 204.

[2] See American Journal of Physiology, vol. xxxi., p. 151.

[3] Ibid., p. 175.

The view of the Federation.—Desiring to meet the needs of the community and the allied professions, the Federation has adopted a policy of neutrality and conciliation. It claims that by no other means than those it provides can the collective voice of a great profession and its allies in the public service be made available in the councils of the nation. Amongst the 45 organisations coöperating at the present time may be mentioned the Royal Society of Medicine, the British Science Guild, the Medical Women's Federation, Medico-Psychological Association, Association of M.O.H., British Dental Association, Pharmaceutical Society, College of Nursing, Royal British Nurses Association, and Midwives Institute—mentioning larger bodies only. And as all the allied professions are fully represented it requires only the coöperation of the British Medical Association and the Medico-Political Union to make adequate representation of medicine possible. Is not this a goal worth some personal sacrifice?

I am, Sir, yours faithfully,
N. HOWARD MUMMERY.

The Federation of Medical and Allied Societies,
5, Vere-street, W. 1., Dec. 21st, 1920.

SPIRITUALISM AND THE NEW PSYCHOLOGY.

To the Editor of THE LANCET.

SIR,—May I congratulate you on having secured for your Christmas Day number a review of Dr. M. Culpin's book on spiritualism by a whole-hogger believer in telepathy? Next Christmas I shall look forward to a number devoted entirely to ghost stories, spirit-rapping, *ouija* boards, &c.—an annual relief from the sobriety of your weekly review of British medicine.

I am, Sir, yours faithfully,
Loughton, Essex, Dec. 29th, 1920. LEONARD HILL.

THE X RAY TREATMENT OF RINGWORM: A WARNING.

To the Editor of THE LANCET.

SIR,—The increasing number of claims against medical practitioners in respect of permanent alopecia following upon the treatment of ringworm of the scalp by X rays renders it desirable that those who may have occasion to use that method of treatment should warn the patient's parents of the possible after-effects.

The violent reaction which occasionally follows even minimum doses of X rays, in spite of all precautions, is otherwise apt to create a suspicion of overdosage or negligent technique, and give rise to claims which might have been avoided by a preliminary word of caution.

I am, Sir, yours faithfully,
JAMES NEAL,
General Secretary.

Medical Defence Union, Ltd., 4, Trafalgar-square,
London, W.C. 2, Dec. 23rd, 1920.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—The annual general meeting of the Medical Officers of Schools Association was held at 2, Savoy-hill, Victoria Embankment, London, W.C., on Dec. 17th, when Mr. R. C. Elmslie was elected president, and thanks were corded to Dr. James Kerr, the retiring president. Having gard to the important position occupied by the journal, nd Hygiene, it was agreed to continue its publication, l Dr. James Kerr and Dr. C. W. Hutt were elected editors. was announced that Dr. E. H. Nash would read a paper School Punishments.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

PARLIAMENT was prorogued on Thursday, Dec. 23rd, until Tuesday, Feb. 15th, 1921. The Royal Assent was given to a number of Acts, including the Women and Young Persons (Employment in Lead Processes) Act and the Employment of Women, Young Persons, and Children Act.

HOUSE OF COMMONS.

MONDAY, DEC. 20TH.

Substitutes for Salvarsan.

Mr. WATERSON asked the Minister of Health if he would furnish the names of the various substitutes for salvarsan and neo-salvarsan the use of which had been approved by his department; and if he would state whether his department guaranteed that the substitutes were exactly similar to the German salvarsan and neo-salvarsan.—Dr. ADDISON replied: The following substitutes for salvarsan and neo-salvarsan have been approved: Kharsivan, neo-kharsivan, arsenobillon, novarsenobillon, diarsenol, neo-diarsenol, galyl, and salvarsan (manufactured by an English firm of chemists). No guarantee of the kind suggested can be given, but there is good reason to believe that all these drugs, with the exception of galyl, correspond in general chemical constitution to the respective German preparations. They are all officially tested for toxicity before being placed on sale.

Dental Bill.

Dr. ADDISON introduced a Bill "to amend the Dentists Act, 1878, and the provisions of the Medical Act, 1886, amending that Act." The Bill was read a first time.

[On Tuesday, Dec. 21st, the order of the second reading of this Bill was discharged and the Bill withdrawn. It is understood that it has been introduced for the purpose of discussion and that it will be re-introduced at the beginning of next session.]

TUESDAY DEC. 21ST.

Ex-Service Men in Asylums.

Mr. LEONARD LYLE asked the Minister of Pensions if his department made any payments in connexion with ex-Service men who were in any asylums whatever in the country for the treatment of mental disease; why, if this was the case, both his department and the Ministry of Health abstained from giving figures; whether the number of such men had been stated officially to be inconsiderable; and whether it was possible, in view of payments made by his department, to give the public reliable information on the matter.—Mr. IAN MACPHERSON replied: I would draw my honourable friend's attention to the replies given to the honourable Member for Frome on June 28th, and to the honourable and gallant Member for Gateshead on July 30th, last. From these it will be seen that ex-Service men, confined in asylums and suffering from certifiable insanity due to war service, are by special arrangements treated as service patients with all the privileges of private patients. Their number on Dec. 9th was, I regret to say, 5634. The entire cost of their maintenance and treatment is borne by my department and, in addition, treatment allowances are made on substantially the same basis as in other cases of in-patient treatment.

Medical Appeal Tribunal for Wales.

Lieutenant-Colonel PARRY asked the Minister of Pensions whether he was aware that the medical appeal tribunal for Wales had been removed from Wales to hear appeal cases in England, and that consequently the hearing of appeal cases in Wales had been suspended, and what was the reason for such action.—Sir G. HEWART (Attorney-General for England) replied: I assume that this question refers to the Pension Appeal Tribunals set up under the War Pensions (Administrative Provisions) Act, 1919. The sitting of the tribunals in various large centres in England and Wales are arranged in accordance with the number of cases received in each district. The tribunal which sits almost continuously in Wales was temporarily removed to London for the fortnight commencing Dec. 6th. It returned to Wales yesterday. The arrangement was the result of (*a*) a diminution in the number of cases received from Wales, and (*b*) an increase in the number of London cases received.

Calves Used for Lymph Production.

Mr. LUNN asked the Minister of Health if he would state how the carcasses of the calves used for the production of vaccine lymph at the Government lymph establishment were disposed of after the lymph had been taken from them and the animals had been slaughtered.—Dr. ADDISON replied: The calves used for the production of lymph at the Government lymph establishment are hired, and after slaughter are examined by the veterinary surgeon of the establishment. The carcasses sold for food are subject to further examination by officers of the local sanitary authorities. I am advised that there is no evidence whatever that the carcasses of vaccinated calves are unfit for food.

Public Vaccination Statistics.

Mr. KENYON asked the Minister of Health if he would furnish a statement showing the number of public vaccinations carried out in England and Wales in each year during the past 10 years, and the expenditure incurred in respect of the same out of national and local funds respectively.—Dr. ADDISON replied: The information asked for by my honourable friend is as follows:—

Year.	Number of successful vaccinations and re-vaccinations performed by public vaccinators at the cost of the rates.	Approximate expenditure incurred in respect of public vaccination.	
		Expenditure out of local rates.	Expenditure out of Exchequer Fund.
1909-10	415,718	£183,000	£25,000
1910-11	394,338	174,000	30,000
1911-12	362,757	165,000	23,000
1912-13	334,530	158,000	19,000
1913-14	315,067	152,000	16,000
1914-15	—	144,000	26,000
1915-16	—	138,000	12,000
1916-17	—	129,000	16,000
1917-18	232,648	116,000	21,000
1918-19	202,913	110,000	20,000

WEDNESDAY, DEC. 22ND.

Food Value of Milk.

Mr. HURD asked the Parliamentary Secretary to the Ministry of Agriculture what steps had been taken to carry out propaganda regarding the food value of milk, as promised six months ago, so as to remedy the insufficient consumption of milk, especially among children.—Dr. ADDISON (Minister of Health) replied: The Ministry of Agriculture and Fisheries and the Board of Education have agreed to coöperate with the Ministry of Health in this matter and have drawn up a scheme for including instruction as to the value and use of milk in various courses at schools and colleges.

Free Passages for Indian Medical Service.

Lieutenant-Colonel RAW asked the Secretary for India if he could make any statement regarding the promised concessions to officers of the Indian Medical Service in the matter of passages to and from India.—Mr. MONTAGU replied: The concession to officers of the Indian Medical Service of free passages to and from this country when sent home on sick leave has been sanctioned with effect from July 1st, 1919.

Committee on Smoke Abatement.

Major HAMILTON asked the Minister of Health whether he had accepted the conclusions of the Committee on Smoke Abatement; and, if so, whether he would explain why in Sheffield and elsewhere contracts for thousands of houses were being approved by his Department without these conclusions being specially brought to the notice of the local authorities concerned.—Dr. ADDISON replied: I have circulated copies of the Interim Report of the Committee on Smoke Abatement to all local authorities with a memorandum recommending consideration of the various substitutes suggested for the open coal fire where these can be economically adopted. The Report has also been brought to the notice of the Housing Commissioners. I understand that in the case of Sheffield the Housing Commissioner has been in touch with the local authority, and that the council are considering the Report with a view to the possibility of taking action in accordance with the suggestions made.

Military Cases of Small-pox.

Mr. RAFFAN asked the Minister of Health if he would state how many naval or military cases of small-pox were reported to his Department during the year 1919; what was the vaccinal condition of the cases; and how many ended fatally.—Dr. ADDISON replied: Four naval cases and 13 military cases of small-pox were reported to my Department during 1909. Four of the patients were stated to have been unvaccinated, and 3 of these cases proved fatal. There was one other fatal case, the vaccinal condition of which could not be ascertained. The remaining 12 cases were stated to have been vaccinated in infancy and one of them to have been revaccinated.

Surplus Hospital Accommodation.

Mr. ORMSBY-GORE asked the Minister of Health whether he would further consult the Association of Poor-law Unions with regard to the best method of rendering all surplus hospital accommodation in Poor-law institutions available for the treatment of the sick before re-introducing Clause 9 of the Ministry of Health (Miscellaneous Provisions) Bill; and whether it was his intention to make any alterations in the Bill before re-introducing it.—Dr. ADDISON replied: I am prepared to consider any suggestions, whether from the Poor-law Unions Association or from any other source, which are consistent with the declared policy of the Government that the treatment of the sick poor should be merged in the general health services of the community. In reply to the latter part of the question, I am not at present aware of any valid reason why the Clause should be altered.

THURSDAY, DEC. 23RD.

Washington Conference and Maternity.

Mr. G. BARNES asked the Minister of Health whether he was yet in a position to state the intentions of the Government with regard to the Washington Conference with respect to maternity.—Dr. ADDISON replied: As my right honourable friend is aware, the views of this Department were communicated some time ago. I understand that questions have arisen affecting international law. They have been referred to the law officers, and the matter is with them at present.—Mr. BARNES: Is it within the recollection of the right honourable gentleman that he has given me that answer almost in exactly similar terms to the same question for the last six months? Will he undertake to speed up the law officers? Is he aware that the Government are under an obligation to put this Convention to the House within 12 months of Jan. 26th last. There may be exceptional circumstances which would justify a postponement, but will he bear that fact in mind and endeavour to get these international law questions settled as speedily as possible? Is it not a fact that international law questions can only arise if the Government intend to put the Convention into operation, and inasmuch as the right honourable gentleman has said that they do not intend to do so, why raise these international law questions at all?—Dr. ADDISON: I really cannot profess to answer questions of international law; I can only say that as far as this Department is concerned its work on this matter was finished some two or three months ago. I understand that the questions are very difficult and intricate. I am advised that important international questions must be settled before the Government can put it to this House, and those are the matters which are causing the delay. I regret the delay, but I know that the law officers are being as expeditious as they can in the matter.

Divisional and Whole-time Medical Officers.

Colonel Sir ARTHUR HOLBROOK asked the Minister of Health if he would state the salaries to be paid to the four divisional medical officers and the 33 whole-time outdoor medical officers recently appointed by him and what he estimated would be their travelling expenses; what expenditure would be incurred for the clerical and nursing staffs for these officers; what payment had been sanctioned for rent and care of regional offices throughout the country; was he aware that the appointment of these officers to supervise and direct panel doctors throughout the country was strongly resented by the medical profession; and, in view of the large expense involved and having regard to the heavy financial obligations already existing, could the matter be reconsidered.—Dr. ADDISON replied: The salary to be paid to the four divisional medical officers is at the rate of £1600 a year, and for the 33 whole-time medical officers the salaries range from £1000 to £1400 a year in all cases inclusive, and providing that no additional payment is made in the shape of war bonus. The total travelling expenses of this staff for a full year is estimated at £8000. In addition a clerk has been assigned in certain areas, and the cost of clerical assistance under this head is estimated at £2700 a year. Where necessary nurses are employed to assist the medical officers at a fee of half a guinea a session. Where it has been necessary to rent premises for this work the arrangements have been made by the Office of Works, but I shall be glad to obtain particulars of cost and furnish them to my honourable and gallant friend. In answer to the last two questions I am certainly not aware that the policy adopted is strongly resented by the medical profession. This policy, which was adopted in 1914, has been continuously supported by medical men and by the Approved Societies; it is sound in itself, and will produce results abundantly justifying the expenditure in the saving of health and of the amounts paid in sickness benefit.

Section 79 of the Lunacy Act, 1890.

Mr. FREDERICK ROBERTS asked the Minister of Health whether he intended to have Section 79 of the Lunacy Act, 1890, posted up in the waiting-rooms of pauper asylums, since this step had been now for some time under the consideration of the Lunacy Board; and, if so, when would this commence.—Dr. ADDISON replied: I am advised that this proposal is by no means free from difficulties, and that there is much difference of opinion among experts as to its advisability. But the Board of Control have now completed their inquiries, and I hope to receive their considered recommendation early in January.

The Care of Lunacy Documents.

Mr. FREDERICK ROBERTS asked the Minister of Health if he could say what became of the original reception order and accompanying medical certificates of inmates who were dead or who have been discharged from asylums, licensed houses, and registered hospitals, and also in the case where a licence was extinguished; did they remain permanently in the keeping of the medical superintendent or licensee; and, in view of the possibility of subsequent legal action taken by a sometime inmate, where the issue might turn upon the integrity and security of these original documents, would he take steps by regulation or otherwise to secure that these originals remained henceforth in the custody of the Lunacy Board and were safe from any interference with their contents.—Dr. ADDISON replied: The original admission papers relating to dead or discharged patients are retained by the authorities of institutions for as long as, in their discretion, they think it necessary. In the case of licensed houses there is no general rule with regard to the custody of documents when the licence is extinguished. But in view of the fact that copies of all these documents are in the possession of the Board of Control, I see no necessity for any regulations of the kind suggested, nor have I any reason to believe that the discretion left to the authorities is not properly exercised.

Medical News.

UNIVERSITY OF CAMBRIDGE: DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—The Special Board for Medicine, on the recommendation of the Committee on Medical Radiology and Electrology, have approved the granting of the Diploma in these subjects to—

Sir A. D. Reid, L.R.C.P. Lond., M.R.C.S. Eng.; R. W. A. Salmond, M.D., Ch.M. Aberd.; H. Martin Berry, M.D. Liverp.; J. F. Hall-Edwards, L.R.C.P. Edin.; and J. T. Case, M.D. Ill.

At examinations held recently the following candidates were successful:—

THIRD EXAMINATION FOR MEDICAL AND SURGICAL DEGREES.

Part I., Surgery and Midwifery.—C. G. Ainsworth and A. B. Appleton, Downing; C. S. Atkin, A. B. Bratton, and W. M. Casper, Caius; M. T. Clegg, Jesus; B. K. T. Collins, Trinity; S. J. Cowell, Queen's; F. C. Cozens, Emmanuel; E. J. Crisp, Sidney Sussex; E. C. Curwen, Caius; H. B. Dodwell and E. A. Fiddian, Emmanual; L. P. Garrod, King's; H. L. Garson, Clare; W. N. Goldschmidt, Pembroke; E. H. H. Granger, Clare; C. Griffith-Jones, Caius; J. C. N. Harris, Pembroke; G. A. Harrison, Caius; F. B. Hobbs, Sidney Sussex; L. W. Jones, Emmanuel; E. I. Lloyd, Trinity; W. H. Palmer and H. A. A. Pargeter, Sidney Sussex; F. P. N. Parsons, Pembroke; P. W. Putnam, Emmanuel; R. S. Scott and T. H. Somervell, Caius; E. D. Spackman, Queens'; G. D. C. Tracy and A. R. Walker, Emmanuel; T. T. B. Watson, Christ's; A. D. Whitelaw, St. John's; V. Wilkinson, Christ's; M. Wong, St. John's; F. G. Wood, Jesus; W. G. Woolrich, St. John's; H. B. Yates, Downing; and K. J. Yeo, Emmanuel.

Part II., Medicine, Pathology, and Pharmacology.—C. G. Ainsworth, Downing; F. Allen and J. C. Andrews, St. John's; C. S. Atkin and S. H. Barnett, Caius; D. C. Beaumont, Christ's; C. C. Beney, Jesus; P. F. Bishop, Clare; C. N. Carter, Trinity; P. D. H. Chapman, Sidney Sussex; A. O. Courtis, Pembroke; S. J. Cowell, Queens'; L. Cunningham, Downing; H. B. Dodwell, Emmanuel; W. D. Doherty, King's; H. V. Edwards, Trinity; L. S. Gathergood, Sidney Sussex; A. C. V. Gosset, Caius; E. H. H. Granger, Clare; J. R. Harris, Queens'; G. A. Harrison, Caius; F. B. Hobbs, Sidney Sussex; L. W. Jones, Emmanuel; J. M. Lawrie, Trinity; P. Lazarus-Barlow, Downing; F. S. Maclean, Jesus; J. W. McK. Nicholl and E. S. Orme, Queens'; R. Y. Paton, Trinity; C. J. Penny, Jesus; K. Playfair and J. L. Potts, Caius; W. B. Purchase, Sidney Sussex; G. P. N. Richardson, Christ's; A. G. Shurlock, Jesus; F. N. Sidebotham, Clare; J. A. B. Snell and P. V. Squires, Caius; W. S. Sykes, Emmanuel; D. C. L. Vey, Clare; H. N. Webber, A. T. Westlake, and A. D. Whitelaw, St. John's; J. Whittingdale, Downing; V. Wilkinson, Christ's; F. R. Winfield, Downing; W. G. Woolrich, St. John's.

UNIVERSITY OF LONDON.—At examinations held recently the following candidates were successful in the subjects indicated:—

M.D. EXAMINATION.

Branch I., Medicine.—Monty Baranov, Univ. Coll. Hosp.; Stanley Batchelor, William Moses Feldman, and Ernest Eugène Herga, London Hosp.; Kenneth Reed Hill, Univ. Coll. Hosp.; Geoffry Charles Lander and Rowland John Perkins, St. Bart.'s Hosp.; Evelyn Dennis Scott, Guy's Hosp.; and James Aubrey Torrens, St. George's Hosp.

Branch IV., Midwifery and Diseases of Women.—Henry William Evans, Guy's Hosp.; and Violet Ione Russell, London (R.F.H.) Sch. of Med. for Women.

Branch V., State Medicine.—Maitland Radford, Univ. Coll. Hosp.

Branch VI., Tropical Medicine.—George Alex Sheridan Madgwick, London Sch. of Trop. Med. and London Hosp.; and Edward Selby Phipson (University medal), Birmingham Univ. and London Sch. of Trop. Med.

M.S. EXAMINATION.

Branch I., Surgery.—Hugh Ernest Griffiths, St. Bart.'s Hosp.; Robert Lister Horton (University medal), Univ. Coll. Hosp.; Samuel Walter Maslen Jones, Middlesex Hosp.; Norbert Leo Maxwell Reader and Cedric Sydney Lane Roberts, Guy's Hosp.; and Henry James Drew Smythe and Douglas George Clutsam Tasker, Bristol Univ. and London Hosp.

UNIVERSITY OF MANCHESTER.—At examinations held recently the following candidates were successful in the subjects indicated:—

FINAL M.B. AND CH.B. EXAMINATION.

F. H. Anderson, May Blakiston, Phyllis M. Congdon, J. W. Crawshaw, A. M. El Aguizy, Florence M. L. Graham, E. M. Greaves, Albert Haworth, G. E. Hayward, Irma M. C. Jehansart, A. W. Kirkham, James Leather, G. H. Lees, Gertrude B. Leigh, P. B. Mumford (second-class honours and distinction in Obstetrics and Surgery), Terence O'Brien, Florence G. Sherry, Doris A. Taylor, Henry Tomlinson, and Raymond Williamson.

Medicine.—Martha F. Barritt and Violet M. Jewson.

Obstetrics.—T. E. Coope.

Forensic Medicine.—R. J. Allison, Caroline M. Edwardes-Evans, Cecil Nelson, H. D. Preston, and S. J. Woodall.

THIRD M.B. AND CH.B. EXAMINATION.

General Pathology and Morbid Anatomy.—R. S. van Aalten, P. D. Abbatt, Reginald Anderton, J. H. Appleton, Mary W. Atkinson (distinction in Pathology), J. B. Bennett, Doris H. Bentham, Benjamin Broman, G. H. Buckley, E. W. Clough, H. M. Coope, Margaret Derbyshire, O. M. Duthie, Kathleen M. Eastwood, Beatrice L. Ellison, H. E. Emmett, H. P. Fay, J. H. Fletcher, William Geraghty, Doris M. Hardman, Arthur Ingham, E. L. Jones, J. I. Kelly, Nora Mills, Winifred H. Mitchell, Louis Morgenstern, A. C. Newman, Hilda Pratt, G. T. Robinson, Abram Rosenstone, F. H. Scotson, Henry Southworth, G. B. Stenhouse, Leo Unsworth, Emmeline Wade, Margaret J. Warburton, Margaret Wild, James Worthington, and James Yates.

Pharmacology and Therapeutics.—Margaret Derbyshire, Gwendolen A. G. Edwardes-Evans, Richard Handley (distinction in Pharmacology), G. A. Lord, Louis Morgenstern, and Margaret J. Warburton.

Hygiene.—Lionel Boyars, Richard Handley, L. W. Kay, G. B. Lord, and Louis Morgenstern.

FINAL EXAMINATION FOR DIPLOMA IN DENTISTRY.

Alan Booth, Dorothy Marsden, and Norman Wood.

UNIVERSITY OF ST. ANDREWS.—At recent examinations the following candidates passed in the subjects mentioned:—

THIRD PROFESSIONAL EXAMINATION FOR M.B., CH.B. DEGREES.

Forensic Medicine and Public Health.—David A. K. Cassells, George R. M. Cordiner, and William A. Steel.

FINAL EXAMINATION FOR M.B., CH.B. DEGREES.

Margaret Jane Mudie Cuthbert, Jean Helen Dumbreck Fleming, Mabel Hodgson, Frances Lilian Knipe, Margherita Murray Lilley, Christian Elinor Little, and John Bain Macdonald.

CAMBRIDGE AND VIENNA.—A collection is being made among resident members of Cambridge University, graduate and undergraduate, in support of relief work in the University of Vienna, but it is believed that many Cambridge men no longer resident would wish to identify themselves with this attempt to help the greatest seat of learning in Central Europe at this time of most pressing need. The *Times* of Oct. 23rd recorded the death in Vienna from starvation of Professor Max Margules, the great meteorologist, who had been living on a pension of 400 kronen (equivalent to 8*s.*) a month; and it is only too clear that this is not an isolated or exceptional instance. In the coming winter both students and professors (with their families) will be in urgent want of the necessities of life. The Cambridge Executive Committee has asked for £5000, and all assistance which old Cambridge men can give will be needed if this sum is to be reached or even approached. Cheques should be sent to Barclay's Bank, Ltd., Cambridge, made payable to the "Universities' Relief Fund."

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN.—The following appointments have been made by the Council: Sir Leonard Rogers, F.R.S., to be Stuart Mill Lecturer in Tropical Medicine; Miss Dorothy Maughan, M.P.S., to be Lecturer in Pharmacy. The Staff of the London School of Medicine for Women have announced that they will increase their donation to the Appeal Fund for the extension of the Hospital and Medical School from £500 to £1000. The extension is to provide beds for the class of workers who live in small flats or lodgings. For these illness is a haunting dread, as they cannot be nursed where they live, while they are unable to afford the high fees charged by good nursing homes. They can afford the cost of maintenance at the present charge of £4 per week. A few beds are now available for men and women at this charge, and 23 more will shortly be ready. Further accommodation for men, women, and children will be provided as soon as funds permit. Donations and subscriptions should be sent to Sir Francis Leyland Barratt, Bart., Honorary Treasurer, Royal Free Hospital, Gray's Inn-road, W.C.1.

National Association for the Prevention of Infant Mortality.—A congress will be held on Infant Welfare in London on July 5th, 6th, and 7th. Among the subjects to be discussed will be residential provision for mothers and babies; inheritance and environment as factors in racial health; the supply of milk, its physiological and economic aspects. Further particulars may be obtained from the secretary at 4, Tavistock-square, London, W.C.1.

Medical Magistrate.—The name of Dr. Chas. Owen Fowler has been added to the list of magistrates for the borough of Croydon.

Medical Coroner.—Dr. R. L. Guthrie, O.B.E., barrister-at-law, has been appointed coroner for the Eastern District of the County of London. Dr. Guthrie was deputy coroner in N.E. London, when, on the outbreak of war, he joined the R.A.M.C. and served for nearly five years in France and at home. He retired with the rank of lieutenant-colonel.

Instruction in Hospital Administration.—A three months' course of lectures and demonstrations in hospital administration will be given at the Western Hospital, Seagrave-road, Fulham, London, S.W., by Dr. R. M. Bruce, medical superintendent, on Tuesdays and Fridays at 5 P.M. The course will begin on Tuesday, Jan. 4th, and is suitable for those reading for a diploma in public health. The fee for the course is £3 3s., and medical men desiring to attend a course of instruction are required before attending at the hospital to pay this fee to the clerk to the Metropolitan Asylums Board, Embankment, London, E.C., giving their full name and address.

The People's League of Health.—As a result of a meeting held by the League at the Cardiff City Hall on Dec. 15th last, under the chairmanship of the Lord Mayor, at which Sir Bruce Bruce-Porter, Dr. Eric Pritchard, Dr. Mary Scharlieb, and Dr. E. H. Stancomb, representing its Medical Council, were the speakers, a committee was formed to establish the work of the League in Wales. Among those organising the Welsh branch are Professor Edgar Collis, Talbot Professor of Preventive Medicine, Welsh National Medical School; Dr. Ewen J. Maclean, a member of the Consultative Council of the Ministry of Health; and Mr. D. W. Evans, Director-General of King Edward VII. Welsh National Memorial Association. The committee considers the present moment opportune for the furtherance of the work undertaken by the League in developing public demand for health legislation.

Central Midwives Board.—A special meeting of the Central Midwives Board was held at Queen Anne's Gate Buildings, Westminster, on Dec. 21st, 1920, with Sir Francis H. Champneys in the chair. Several midwives were struck off the roll and in two cases midwives were placed on probation, the following charges amongst others having been brought forward:—

> Being in attendance at a confinement and the child suffering from inflammation about the navel, the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as provided by Rule E. 21 (5), and the child suffering from illness supposed to be infectious, the midwife neglected to send to the local supervising authority any notification that she was herself liable to be a source of infection, as required by Rule E. 23 (c). A midwife did not take and record the pulse and temperature of her patients at each visit, as required by Rule E. 14, and she did not enter records of the pulse and temperature of her patients in a notebook or on a chart carefully preserved, as required by Rule E. 14. A midwife neglected to wash the patient's external parts with soap and water and to swab them with an efficient antiseptic solution before making the first internal examination, as required by Rule E. 8 (a); she did not disinfect her hands and forearms before touching the patient's generative organs, as required by Rule E. 4; she neglected to take and record the pulse and temperature of the patient at each visit, as required by Rule E. 14; and medical aid having been sought for the patient and child, she neglected to notify the local supervising authority thereof, as required by Rule E. 22 (1) (a). Without undergoing disinfection to the satisfaction of the local supervising authority a midwife continued in attendance upon other maternity patients, contrary to Rule E. 6. A patient suffering from excessive bleeding, the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as provided by Rule E. 21 (3), and the patient's mother desiring the attendance of a registered medical practitioner the midwife dissuaded her from securing his attendance (misconduct).

At a meeting of the Board held on the same day a letter was considered from Miss Clive Haydon, the honorary secretary of the Teachers Instruction Course Midwives' Institute, stating that the teachers of midwifery who attended the recent course of instruction at the Institute had passed resolutions urging the extension of the period of midwifery training and the advisability of a high qualification for approved teachers. The Board agreed with the advisability of raising the standard of midwifery training both for pupils and teachers whenever circumstances render such an advance practicable. Meanwhile any such voluntary extension of the duration of training would meet with the hearty approval of the Board.—A letter was considered from the medical officer of health for Kensington, asking if, in the event of the Kensington Council arranging for the nursing of a mother and child (the latter suffering from ophthalmia neonatorum) to be taken over by a midwife specially engaged by the council for the purpose, the midwife originally engaged would be discharged from all responsibility during the period subsequent to such taking over. The Board decided that the medical officer of health for Kensington be informed that the Board thinks that an arrangement whereby a nurse specially trained is available for bad cases of ophthalmia neonatorum would be very helpful, but does not think that midwives should be separated either from mothers or children under their care.—A letter was considered from the medical officer of health for the city of Worcester asking if it is considered desirable that investigation of the mode of practice of a midwife under Rule E. 25 should be carried out in the case of all midwives or only in those cases where the results of the midwife's work have not seemed satisfactory. The Board decided that the medical officer of health for Worcester be informed that Rule E. 25 (p. 37) reads as follows:—

> "The local supervising authority shall make arrangements to secure proper inspection of the register of cases, bag of appliances, &c., of every midwife practising in the district of each authority, and, when thought necessary, an inspection of her place of residence and an investigation of her mode of practice."

This rule obliges the local supervising authority to secure a proper inspection of the register, &c., of every midwife, but leaves the inspection of the residence and mode of practice to the discretion of the local supervising authority. It is highly advisable that unnecessary inspection should be avoided as likely to annoy the patient, to cast doubt on the efficiency of the midwife, and generally to interfere with the working of the Act.

Fees of Doctors Called in by Midwives.—A new scale of fees for the payment by local supervising authorities of medical practitioners called in by midwives under Section 14 of the Midwives Act, 1918, has come into operation to take the place of that prescribed by the Local Government Board in December, 1918. The chief alterations made by the new scale are:—

> (1) The fee for attendance at confinements is £2 2s. in all cases, instead of £1 1s. in ordinary cases, and £2 2s. in cases involving operative assistance.
>
> (2) A special fee of £1 1s. is prescribed for suturing the perineum and for other operative assistance occurring after the confinement, and also for attendance at abortions or miscarriages.
>
> (3) The fee for visits is increased to 5s. by day and 10s. by night.
>
> (4) It is made clear that a fee is not payable by the local supervising authority where the doctor has agreed to attend the patient under arrangement made by or on behalf of the patient or by any club, medical institute, or other association of which the patient or her husband is a member, or where the doctor receives or agrees to receive a fee from the patient or her representative, or in respect of any services performed by the doctor after the expiry of four weeks from the day of birth.

The Minister of Health has approved an alteration in the rules of the Central Midwives Board, which makes Section 14 of the Midwives Act applicable to all cases in which a midwife calls in a doctor under the C.M.B. rules. Rule E.20 now reads:—

> In all cases of illness of the patient or child or of any abnormality occurring during pregnancy, labour, or lying-in, a midwife, as soon as she becomes aware thereof, must call in to her assistance a registered medical practitioner, using for this purpose the form of sending for medical help properly filled up and signed by her. The conditions referred to in this rule shall be deemed to be emergencies for the purpose of Section 14 of the Midwives Act, 1918.

The local supervising authority is, of course, empowered to recover these fees except in cases of poverty.

The late Dr. G. C. Grant.—George Cowie Grant, of Dufftown, died in a nursing home in Aberdeen on Dec. 23rd. He was the fifth son of Major William Grant, of Balvenie House, Dufftown, and brother of the late Mr. J. Grant, well known as county clerk of Banffshire and town clerk of Banff. Dr. Grant was a graduate of Aberdeen University and took the degree of M.B. and C.M. in 1894. He afterwards practised his profession in England for about two years at Birmingham City Asylum and for six years as a practitioner in Colne, Lancashire. In 1902, for personal reasons, he gave up his professional career, but did not cease to take an interest in health matters. For a number of years he was chairman of the isolation hospital at Dufftown, convener of the public health committee of the county council, and chairman of the board of control. For a term of three years he was provost of Dufftown. He was also a member of the county council and a justice of the peace for the county. About two years ago he was appointed convener of the county of Banff. Dr. Grant took a deep interest in all that pertained to the welfare of the community and was everywhere held in high esteem. He is survived by a widow and family.

MEDICO-LEGAL SOCIETY.—A meeting of this society will be held at 11, Chandos-street, London, W., on Tuesday, Jan. 18th, at 8.30 P.M., when a paper will be read by Dr. H. Gibson Sutherland on Medical Evidence in the Staunton Murder Trial.

SOCIETY FOR THE PREVENTION OF VENEREAL DISEASE.—The Executive Committee of the Society for the Prevention of Venereal Disease has recently been enlarged by the inclusion of the following members:—Mr. W. Willson Cobbett, Captain W. E. Elliot, M.P., Dr. A. Mearns Fraser, Dr. Jane Lorimer Hawthorne, Mr. Cuthbert Laws (General Manager of Shipping Federation), Mr. Harry Machin, Captain T. Michell, R.N., Surgeon Vice-Admiral Sir James Porter (late Director-General, Naval Medical Department), and Mr. A. H. Tubby, F.R.C.S.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee held on Dec. 14th, 1920, 30 cases were considered and £315 voted to 25. The following is a summary of some of the cases relieved.

Daughter, aged 61, of M.R.C.S Eng. who practised in London and died in 1885. Her mother, who died in 1906, and self were left with very limited means. The applicant now has only £1 per week, and owing to ill-health and increased cost of living finds it impossible to pay her way and has got into debt. Highly recommended.—Widow, aged 71, of M.D. Glasgow who practised in Scotland and died in 1889. Lives with a sister who has £10 and applicant has £50. They endeavour to supplement this by letting rooms, and last year received from this source £65. Rent £34.—Widow, aged 75, of M.R.C.S. Eng. who practised in Brixton and died in 1883. Applicant was left totally unprovided for with four children, all of whom are married and unable to assist her. Only income the Old-age Pension, 10s. per week, and occasional gifts from friend. Pays 8s. per week for one room. Relatives who in the past helped are now all dead.—Widow, aged 31, of M.B. Edin. who had for two years worked on a Pensions Board and previously worked as a locum tenens and died in 1920. Applicant left quite unprovided for with two children, ages 4 and 5. Deceased's colleagues on the Pensions Board collected a sum of money to assist applicant, but this will soon be exhausted. Having to look after the children she cannot undertake a post. Would like to get the children into a home. Expenses: Rent £1 per week; board, 25s. per week; storage of furniture, 5s.—Widow, aged 41, of M.R.C.S. Eng. who practised at Plymouth for over 30 years and died in September, 1920. Applicant left with son, aged 12, and girl, 10, with insufficient means. Health bad, so unable to work. Certain income about £35, and has had to spend some of her capital to pay her way. Rent 16s. per week.

Subscriptions may be sent to the honorary treasurer, Sir Charters J. Symonds, C.B., F.R.C.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

OUTBREAK OF SMALL-POX IN ABERDEENSHIRE.—Two cases of small-pox from the Longside district of Aberdeenshire were admitted into the County Infectious Diseases Hospital at Aberdeen on Dec. 22nd. The outbreak took place in a family at Rova, and its origin is as yet unknown. The persons affected are men, aged 66 and about 21. The diagnosis has been officially confirmed.

HEALTH SCHEME FOR THE COUNTY OF ABERDEEN.—The proposals of the Scottish Board of Health in connexion with maternity service, child welfare, and the general public health administration of the county have been under consideration by a special committee of the Aberdeen County Council. The Council is recommended to appoint Dr. H. J. Rae, the tuberculosis medical officer for Aberdeenshire, to the office of deputy M.O.H. for the county, and to continue his present administration of the tuberculosis scheme for the combined area, and also to act as administrative and executive officer under the new scheme. Dr. Rae is also recommended for the post of inspector of midwives under the scheme. The Committee recommends that the salaries of Dr. J. P. Watt and Dr. Rae be increased by £200 each from May 15th last, subject to the approval of the Scottish Board of Health, the increase in the case of Dr. Rae to be charged against the scheme for maternity service and child welfare. Nursing associations are proposed for every district, so that the total number of nurses in the county would amount to 31.

DONATIONS AND BEQUESTS.—Under the will of the late Mr. F. Gorringe, who left £450,000 for charitable purposes, subject to the life interest of his wife, whose death was recently announced, the St. George's Hospital and the Westminster Hospital will receive an eighth share each.—*Manchester Hospitals:* £5000 were received by the Salford Royal Hospital towards the cost of the new nurses home, as a thank-offering from Edward Pilkington, Laurence Pilkington, and Mary Gavin Pilkington. A legacy of £1000 from the executors of the late Mr. Lewis Atkinson, of Higher roughton, was also received. It was decided to name a bed er the donor. From the Dickenson Charity £200 were ived to be applied as income for present neces- s, and £100 from Mrs. Lomas Harrison, of Hale. St. Mary's Hospitals have received from the executors he late Mr. Lewis Atkinson £900, and from those of the late Mr. W. Cooney £73. A sum of £1000 has also been received from Mrs. E. Lees for the endowment of a bed, and £750 from the Anson Golf Club for the endowment of a cot. Further donations to the amount of £325 have also been received by the board of management.—*Hospitals in the North of Scotland:* The employees of the Great North of Scotland Railway met recently to consider the allocation of the money which had been collected during the year on behalf of local charitable institutions. The chairman reported that the sum of £432 9*s.* 5*d.* had been collected over the system among the traffic, permanent way, and head office staffs. Over 95 per cent. of the staff had contributed to the collection. He added that the Board of Directors had announced their intention of giving a subscription of £200 to the Aberdeen Royal Infirmary. The money collected was allocated as follows: Aberdeen Royal Infirmary, £432; Sick Children's Hospital, £30; Eye Institute, £5; Chalmers's Hospital, Banff, £15; Gray's Hospital, Elgin, £15; Turner Memorial Institute, Keith, £15. The collections made by the employees of the Northern Cooperative Society amount to £150, an increase of 50 per cent. Most of the employees now make weekly contributions. The sum of £150 was allocated as follows: Royal Infirmary, £75; Royal Hospital for Sick Children, £20; Aberdeen District Nursing Association, £10; Eye Institution, £7; Morningfield Hospital, £5; Convalescent Hospital, Newhills, £10; Convalescent Hospital, Cults, £10; Aberdeen Dispensary, £8; and the Asylum for the Blind, £5. £1362 have now been contributed by the employees since the fund was started. The school teachers of Aberdeen have set an excellent example to other members of the community in subscribing the handsome sum of £425 15*s.* 1*d.* to Sir James Taggart's scheme for assisting the Sick Children's Hospital. This represents more than four hours' pay. Many teachers gave a whole day's pay.

MANCHESTER UNIVERSITY DEGREE DAY.—Degrees were conferred on Dec. 22nd by the Vice-Chancellor on a number of graduates. For the first time in the history of the University the degree of Doctor of Philosophy was awarded, the recipient having done research work in organic chemistry. Of the 21 Bachelors of Medicine and of Surgery seven were women.

ABERYSTWYTH DISTRICT MEDICAL OFFICERSHIP.—The deadlock between Aberystwyth guardians and the Ministry of Health, on which we have already commented (THE LANCET, Nov. 27th, p. 1119, and Dec. 25th, p. 1328), advanced another stage at a meeting on Monday. At the last meeting of the guardians an intimation was received from the Ministry of Health that the salary of Dr. J. A. Rees, who had been appointed in preference to Dr. A. Thomas, who served throughout the war, would not be sanctioned by the Ministry, and it was agreed to ask Dr. Rees for his views on the subject. Dr. Rees replied that he left the matter in the hands of the majority of the board. The clerk now explained that it would be necessary to appoint a temporary medical officer, and the majority of the guardians promptly reappointed Dr. Rees as temporary medical officer.

CARDIFF MEDICAL SOCIETY.—At a meeting of this society on Dec. 14th, 1920, specimens were shown. Mr. Geary Grant showed: (1) an Appendix and a Meckel's diverticulum which had become adherent to the mesentery of the ileum, removed from a case which had been admitted with signs of acute appendicitis; (2) three small Epithelial Inclusion Cysts from a patient who had suffered an injury to the finger; they were found lying on the tendon sheath, simulating a ganglion; (3) a Thyroid suspected of being malignant, removed June, 1920, from a patient who had returned with a freely movable gland in the neck, which he proposed to remove. Dr. D. R. Paterson discussed the effect on the voice of removing the thyroid, and reported a case of complete paralysis of the vocal cords requiring a tracheotomy tube. Mr. Tenison Collins showed: (1) a Pediculated Fibroid Tumour, partly cartilaginous, removed from the anterior surface of the fundus uteri from a patient suffering severe menorrhagia with the uterine wall otherwise normal; (2) a Phosphatic Stone, weighing 4 ounces, from a woman suffering from retention of urine, removed by vaginal cystotomy, one end of which appeared to have fallen on the urethra, acting as a valve; (3) the Handle of a Crochet-hook, slightly sharpened, from a woman three months' pregnant, located by X rays and found lying in the utero-vesical pouch, causing no sign of irritation, the insertion and removal of which had no effect on pregnancy. Mr. Geary Grant reported removing a phosphatic mass round a nucleus of "slippery elm" by suprapubic cystotomy. Mr. J. O. D. Wade showed an Oxalate of Lime Vesical Calculus from a boy aged 19 years, who passed urine every half hour, the history dating from birth. A sound would not enter the bladder. The calculus was removed by suprapubic cystotomy with great difficulty, owing to the sharp spicules fitting into folds of the mucous membrane.

THE Secretary of State, Home Office, S.W., gives notice of a vacancy for a Certifying Surgeon under the Factory and Workshop Acts at Caterham.

Births, Marriages, and Deaths.

BIRTHS.

WALLACE.—On Dec. 7th, 1920, in Calcutta, the wife of Captain Q. V. B. Wallace, M.C., R.A.M.C., of a son.

WHEELER-BENNETT.—On Dec. 22nd, 1920, at "Grenofen," Steyning, Sussex, the wife of Dr. Clement Wheeler-Bennett, of a son.

WHITE.—On Dec. 12th, 1920, at 1, Albemarle-road, Withington, Manchester, the wife of Charles Powell White, M.D., F.R.C.S.—a daughter.

WIGHT.—At Swatow, China, on Nov. 14th, 1920, to Dr. and Mrs. A. Wight, English Presbyterian Mission—a daughter.

MARRIAGES.

HEATON—WHEELER-BENNETT.—On Dec. 21st, 1920, at St. Luke's Church, Bromley Common, Kent, Trevor Braby Heaton, O.B.E., M.D., M.R.C.P., to Constance Irene, only daughter of J. W. Wheeler-Bennett, C.B.E., J.P., and Mrs. Wheeler-Bennett, of Ravensbourne, Keston, Kent.

JOHNSTONE—DEMPSTER.—On Dec. 21st, 1920, at St. Ninian's Cathedral, Perth, George Gordon Johnstone, M.C., M.D., D.P.H., to Constance Margaret, eldest daughter of Mr. and Mrs. T. Dempster, of Perth.

LAWRENCE—GOODRIDGE.—On Dec. 20th, 1920, at St. Andrew's Church, Bournemouth, Sidney Cameron Lawrence, M.B., Ch.B., D.P.H., to Maria Louisa, widow of John Perch Goodridge.

DEATHS.

DOUGLAS.—On Dec. 22nd, 1920, at Devonshire-street, Portland-place Arthur Douglas, M.D., Senior Physician, British Hospital for Mental Disorders and Nervous Diseases, aged 70.

JOHNSTON.—On Dec. 22nd, 1920, at Braehead, Lugar, Ayrshire, Robert Johnston, M.B., C.M., late of Dundee, in his 74th year.

MAIR.—On Dec. 21st, 1920, at Westbourne-terrace, W., Robert Slater Mair, M.D., in his 95th year.

MARSDEN.—On Dec. 19th, 1920, at St. Thomas's Hospital, London, after a long and painful illness contracted on active service, Walter Gibson Marsden, M.A., M.B., B.Ch., late Captain, R.A.M.C.

NEAL.—On Dec. 23rd, 1920, at Bolingbroke-grove, S.W., John Breward Neal, M.R.C.P., in his 73rd year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Wednesday, Jan. 5th.

SECTION OF SURGERY: at 5.30 P.M. (Exhibits at 4.30 P.M.)

Paper:

Mr. James Berry: A Further Series of 500 Goitre Operations, with Special Reference to After Results (illustrated by the epidiascope and demonstration of patients).

Abstracts of the notes with temperature and pulse charts of every case will be exhibited, together with a large number of pathological specimens, which will be on view at 4.30 P.M.

The meeting will be of great interest to the members of the Sections of Medicine and Laryngology.

Thursday, Jan. 6th.

SECTION OF OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Short Communication:

Dr. Louise McIlroy: The Use of Morphia in Labour.

Paper:

Mr. Percival Cole: A Series of 43 Cases of Inoperable Uterine Carcinoma treated by the Cold Cautery Method of Percy.

Tuesday, Jan. 11th.

SECTION OF PSYCHIATRY: at 8.30 P.M.

Paper:

Dr. Morowoka: The Morbid Conditions of the Choroid Plexus in Mental Disease (illustrated by epidiascope).

Thursday, Jan. 13th.

SECTION OF NEUROLOGY: at 8.30 P.M.

Informal Meeting for free discussion (tea, coffee, smoking).

N.B.—As this is the first of these evenings it is hoped that Members will endeavour to attend and, if possible, exhibit objects of interest.

Friday, Jan. 14th.

CLINICAL SECTION: at 5.30 P.M. (Cases at 5 P.M.)

Cases: The following will be shown by—

Mr. W. E. Tanner: Case of Osteochondritis Deformans.

Mr. W. H. Ogilvie and Mr. Massie: Two Cases of Fracture-Dislocation of the Ankle.

Mr. Bonar: Impacted Fracture—Separation of Lower Epiphysis of the Femur.

Other cases will be shown.

SECTION OF OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)

Cases and Exhibits:

Mr. G. Winfield Roll: Foreign Body Retained in the Eye for Many Years.

Mr. B. T. Lang: A New Scotometer.

Papers:

Dr. Ransom Pickard: Variations in the Size of the Physiological Cup, and their Relation to Glaucoma.

Mr. B. T. Lang: Scotometry.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Jan. 3rd.—2 P.M., Dr. G. Stewart: Medical Out-patients. Mr. MacDonald: Surgical Out-patients. Dr. Simson: Diseases of Women. Dr. Morton: X Ray Department.

TUESDAY.—2 P.M., Dr. Burnford: Medical Out-patients. Mr. T. Gray: Surgical Out-patients. Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Skin Department.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. Addison: Operations. Mr. Gibb: Eye Department. Mr. D. Armour: Visit to Surgical Wards.

THURSDAY.—2 P.M., Dr. G. Stewart: Medical Out-patients. Mr. D. Armour: Operations. Mr. B. Harman: Eye Department. Mr. Baldwin: Orthopædic Department.

FRIDAY.—10 A.M., Mr. D. Buxton: Dental Department. Dr. McDougal: Electrical Department. Dr. Robinson: Gynæcological Operations. 2 P.M., Dr. Burnford: Medical Out-patients.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Sinclair: Surgical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, Jan. 6th.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: Eczema.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

Christmas Lectures on the Haunts of Life, by Prof. J. A. Thomson:—

TUESDAY, JAN. 4th.—3 P.M., Lecture III.:—The Great Deeps.

THURSDAY.—3 P.M., Lecture IV.:—The Freshwaters.

Notes, Short Comments, and Answers to Correspondents.

SOME PROBLEMS IN MARINE HYGIENE.[1]

WITH SPECIAL REFERENCE TO MERCHANT SHIPS.

BY SURGEON VICE-ADMIRAL SIR ROBERT HILL, K.C.M.G., C.B., C.V.O.,

MEDICAL DIRECTOR-GENERAL OF THE ROYAL NAVY.

I. VENTILATION AND ACCOMMODATION IN SHIPS.

The Foundation of Naval Hygiene.

THE most prominent pioneers of naval hygiene were three medical officers—James Lind, who began his sea service in 1739, and two others, Thomas Trotter and Gilbert Blane, who began theirs in 1779. These three were men of widely different characteristics, but they had in common the aspiration to improve the health of our seamen and the sanitary conditions under which they lived. Lind—methodical [illegible] painstaking, far-seeing in his suggested improvements could not stand against opposition and became r[illegible] Trotter, impetuous and a fighter, obtained minor reforms, Blane, full of worldly wisdom and tact, ingratiated himself with the authorities—who were absolutely ignorant of naval hygiene—and won them over to his side. These pioneers set themselves to eradicate diseases in the fleets and merchant ships and to bring the general conditions of living to some degree of sanitation.

The personnel was chiefly ravaged by scurvy, small-pox, and typhus, which sometimes carried off four-fifths of a naval or mercantile expedition. Reforms were hard to enforce; even when lime-juice became known as preventive of scurvy, and vaccination had proved its value in combating small-pox, very little advantage was taken of either. In 1761 Lind introduced the distillation of sea-water to make drinking-water, but distillation was probably adopted in very few ships at that time. He, no less than Trotter and Blane, was convinced of the necessity of ventilation and cleanliness, recognised that infection of certain diseases was carried by personal contamination and by clothing, and advocated isolation of infected persons and the fumigation of closed compartments. Trotter believed in vaccination against small-pox, then a terrible scourge in the Navy, but not until 1800 was an Order issued permitting surgeons to vaccinate seamen who desired it. In 1795 Blane became one of the two Medical Commissioners on the Board of Sick and Wounded Sailors; owing to his efforts the general use of anti-scorbutics became obligatory in the following year. He paid particular attention to the seaman's diet, recognising that it was not salt that caused scurvy, but a deficiency of other things in diet, a fact that is now well understood to be a cause of other diseases, such as beri-beri. In this way the foundations of marine hygiene were laid; we now recognise that most of the general principles of hygiene observed on shore can also be applied to men afloat in the Navy or Mercantile Marine, although the ship is still subject to particular limitations of size, occupation, and climate.

Ventilation.

Efficient ventilation of a ship is perhaps the most difficult problem of marine hygiene. Pryor has likened a ship to a bottle, through the neck of which fresh air has to come in and foul air escape. At one time wind-sails were the only means of artificial ventilation known. These are, in the words of Blane, "wide tubes formed of canvas and extended by hoops into the form of a cylinder, which pass from the external air into the lower parts of the ship through hatches"; but when the ship was battened down they could not be used. As far back as the end of the seventeenth century square wooden trunks, subsequently replaced by brass trunks (the idea being borrowed from a French frigate) were conducted from the hold or lower deck to the open air; this was the germ of origin of our present excellent system. At the present time it is stated in the Board of Trade instructions that in merchant ships "no hard-and-fast rule can be laid down as to the system of ventilation to be adopted ...... but that there should not be less than two ventilators, one serving as an inlet for the admission of fresh air, and the other as an outlet for escape of impure air." These must be fitted clear of bunks, so as not to cause discomfort to occupants. "To ventilate forecastles, poops, and between deck spaces, the simplest method is to have an iron pipe with revolving cowl at each end of the space, so that while impure air escapes at one end pure and fresh air will enter at the other, and a constant circulation be kept up. One of the ventilators should pass through the deck to at least the lower edge of the beams," but it may be remarked here that it would be better to carry the inlet pipe down to near the deck of the space so that fresh air may circulate right through the space. For the tropics means of introducing windsails by some aperture, such as a skylight or hatch being cut in the deck over the living space, are insisted on. The instructions state that when it is proposed to ventilate crew spaces by any system of mechanical ventilation the full plans to scale should be forwarded for the Board's consideration by the surveyor. There is no mention of consultation with a medical officer, but I consider that the advice of a medical officer expert in ship's hygiene should always be taken; such an expert should sit on the Board of Construction of all ships. In the Royal Navy a medical officer of the Medical Director-General's Staff inspects the ventilation of ships under construction, and coöperates with other Departments in dealing with proposed alterations and improvements; but the ideal would be attained if this officer attended the meetings of the Board of Construction before the keel of a ship was laid. The medical officer is nearly always called in too late for his recommendation to be carried out except at enormous expense. I understand that in France the plans of every ship proposed to be built must be submitted to a Board of Construction, which includes "The Director of Public Health." I must, however, insist that until a medical officer has had long experience at sea, whether in the Royal Navy or Mercantile Navy, he is not qualified to give valuable and practicable advice on construction.

---

[1] Being portions of a Chadwick Trust lecture delivered at Newcastle-upon-Tyne, Dec. 3rd, 1920.

Efficient ventilation in merchant ships, whether natural or artificial, is not so difficult as in men-of-war. The main object of the latter is fighting efficiency, and with all the increasingly complicated and necessary machinery it became a very difficult problem. In 1912 a special committee was able to overcome many difficulties; time and experience gained will, we hope, soon solve the remainder.

Essentials necessary; systems employed.—To obtain efficient ventilation three essentials are necessary: (1) the circulation of a sufficiency of fresh air; (2) the distribution of air without creating draughts; and (3) the maintenance of an equable temperature. Three systems are available for artificial ventilation in a ship—the Plenum system, the exhaust system, and the system where these two are combined. In the Royal Navy the Plenum system is now mainly adopted by which air is drawn in from outside, the inlets being placed on the upper deck so that no foul or exhaust air can be sucked into them; it is then forced by powerful electric fans through air trunks to the living spaces. If necessary it can be warmed by use of "thermo-tanks," which consist of a series of steam pipes over which the cold air passes and is so warmed before passing into the trunks; by these mechanical means the temperature of the air can be adjusted to the comfort of the men.

Standard of purity.—In living and working spaces of a ship a high standard of purity of air must be aimed at. In H.M. ships the fans for supply and the air-trunking are designed to provide for the supply and suitable distribution of air at the rate of 50 cubic feet per person per minute, or 3000 cubic feet per hour. In order to obtain this delivery of fresh air to all parts of the space, outlet gratings of fixed expanded steel are placed at regular intervals along the supply trunks, which extend to the farthest part of the space, the trunk end being closed. Inside the trunks straight metal deflectors are placed near these openings; by adjustment of these deflectors a uniform velocity at all parts is obtained, no unpleasant draught being experienced at a distance of 1 foot from the grating even when 100 cubic feet per minute issue from it. When such equality of velocity is obtained after various trials these deflectors are permanently fixed. It has now been definitely settled that in spaces where there are foul odours or gases or vitiated atmosphere the exhaust system is only to be used. This is a useful point for merchant ships carrying dangerous cargoes of coal or oil and should be considered in the construction for the ventilation of holds. Some merchant ships—as, for instance, the *Aquitania*—employ the double or interchangeable system of supply and exhaust; but the latter is open to the criticism that the exhaust trunks accumulate dust and dirt, which if the exhaust be reversed into supply is blown into the compartment again. It is, however, in smaller ships that the problem of ventilation is so urgent. The Board of Trade instructions only deal with the rudiments of the problem; cowl ventilators (inlet and outlet) frequently have to be closed during bad weather, ventilation then ceasing to exist. Dr. William Hanna, of Liverpool, has rightly advocated the adoption of an electric fan, running at two speeds, fast and slow, and driving air into a shaft which would be carried into and around the quarters at a lower level than the bunks. The shaft is perforated with numerous small holes to admit air into the forecastle. I must emphasise this point. No seaman, naval or mercantile, will stand a draught, and no draught would be experienced if the velocity were not more than 3 feet per second; outlet shafts should be fixed in suitable positions.

Some system of warming the fresh air-supply is necessary; the temperature to be aimed at is about 55° to 60° F.—higher than which it tends to produce dryness of the nose and throat, headache, and fatigue. In H.M. ships the fresh air is heated by being driven through thermo-tanks containing tubes through which steam passes at low pressure. A by-pass is fitted to allow supply of cold air when required; if well regulated its effect will be to prevent excessive moisture and excessive dryness. This method would only be practicable in the larger merchant ships; some system of radiators, electric or steam, should therefore be provided. For cubicles, cabins, and small living spaces an ordinary electric table fan of the traversing type will do much to remove "stuffiness."

Inspection.—Merchant ships carrying medical officers should have a system of inspection of ventilating arrangements, samples of air being taken from time to time with observations on the wet and dry bulb thermometer of the outside and inside air for comparisons; these samples should be sent for analysis. The standard of purity of air laid down in H.M. ships is that there shall be in a living space not more than 12 parts of carbonic acid gas to 10,000 parts of air.

Accommodation.

This subject has aroused perhaps the greatest controversy among all the problems concerning the merchant service. The Merchant Shipping Act at present in force lays down that each man shall have 120 cubic feet air space and 15 square feet floor space. The Act says space occupied by messrooms, bathrooms, or washing places appropriated to the use of seamen may be taken into account, so that not less than 72 cubic feet and 12 square feet is obtained for each man. This should be "over all," that is to say, not counting in space filled up by fixtures. The Australian Government gives 140 cubic feet and 18 square feet; the Norwegian Government gives 125 cubic feet and 18 square feet, exclusive of fixtures, cupboards, &c. In the Royal Navy 200 cubic feet are allowed per man, but this is where hammock-slinging is general. The merchant seaman appears to wish for the "bunk or berth system" for sleeping. The main objection to this system is that it is seldom feasible to provide a separate bunk for each man; a bunk is usually occupied by different men in various watches—an objectionable habit and likely to lead to spread of infectious and contagious diseases. Hammocks, one for each man, are much more hygienic; they are stowed away when not in use, space for day living and messing being thus opened up. The bedding is more easily inspected and each man is responsible for the cleanliness of his own. I feel sure the general adoption of hammocks will lead to better health and comfort. I understand the cubicle system is asked for, with iron bunks; the latter proviso is agreed to, as wooden bunks harbour vermin; but iron bunks, if adopted, should be made to fold up when not in use, especially where no separate messing space is allowed for.

Living space forward or aft.—As regards the placing forward or aft of living spaces for men it is stated that the forecastle position is exposed to storm, danger through collision, cessation of ventilation in bad weather, and noise, which in head seas interferes with sleep. On the other hand, the seaman is much less overlooked "for'ard" and can lead his own life; in hot and calm weather the forecastle is in a favourable position; the best place on board in a collision is governed by chance; and the commanding officer prefers his men for'ard as being more under control in case of accidents. Aft, the noise of the propellers is trying and "bumping" still occurs in heavy seas. On the whole, the aft position is perhaps better; it was lately adopted in H.M. ships, but was not popular with the men, although many officers preferred it. But this comparison hardly holds on account of different structure. On the subject of hammock-slinging it is interesting to note that recently an inquiry was held by the Ministry of Transport and Shipping in conjunction with the Admiralty and War Office on the evil effects of spacing hammocks too near each other in H.M. transports. This spacing was formerly 16 inches between each hammock hook; in the Royal Navy it has now been increased to 20 inches. The evils of such close approximation in transports were revealed in their overcrowded state during the war; influenza spread to an alarming extent and mortality was high. In future hammock hooks will be fitted 27 inches apart, centre to centre, instead of 16 inches, and the interlocking of the hammocks will be increased from 3 feet to 4 feet 6 inches. Troops will be embarked up to the extent of the hammock billets provided, plus 25 per cent. in addition. By the new method of slinging no two heads of people in adjacent hammocks are opposite. The 25 per cent. troops for whom no hammock billets are provided will be employed on various duties (sentries and watch-keepers) whilst the remainder are sleeping.

General accommodation.—On the subject of general accommodation in merchant ships I recommend for your perusal the February, 1920, publication of *Blackwood's Magazine*, which contains the impressions of a naval officer on first taking over command of a merchant ship for war service. It is satisfactory to note that the merchant seamen gladly adopted the disciplinary measures which were made for their comfort. This shows how much can be done to improve living conditions by officers of a ship provided they have the necessary knowledge and tact. Much more, however, could be done if ship-owners and ship-builders would make every effort to improve sanitary conditions, thereby making the men more contented and getting better work from them. This is evidenced in the new standard ships. Here the crew are placed in the after-part of the ship, which is steam-heated. Messing space is separated from the sleeping space; a recreation- and smoke-room is provided; cubic and floor space is more than is laid down by the Board of Trade. Separate cubicles, each fitted with two berths, are placed along the ship's side. The men wish them placed against the bulk-heads, but I think the former is the better arrangement. Seamen and firemen's wash-places are provided and have lockers for each man's dirty clothing. I think the adoption of spray-baths would be a further great improvement, saving water and time and meaning that no man can wash in the same water another has used. These improvements have their origin in the demands made by the National Seamen's and Firemen's Union.

THE NATURE OF ANIMAL LIGHT.

WITHOUT discussing the ultimate nature of light—whether it is due to a succession of pulse-waves in the ether caused by vibrations of electrons or to other causes—there are aspects of the question, more especially bio-luminescence or bio-photogenesis—the production of light by animals and plants—which have in all ages excited the interest and curiosity of mankind. Professor E. Newton Harvey, of Princeton University, has published a most interesting monograph—one of the series of "Monographs on Experimental Biology"—on the "Nature of Animal Light."[1] The memoir is concerned largely with the physical characteristics of animal light and the chemical processes underlying its production. Recent researches go far to place this question on a sound physico-chemical basis. That animals can produce light was recognised in the earliest times, when fire-flies and glow-worms abounded and the phosphorescence or "burning of the sea" was described by the older explorers. Aristotle mentions the light emitted by dead fish and flesh and some kinds of damp wood—phenomena now proved to be due to living micro-organisms.

Bio-luminescent Animals and Plants.

In 1667 Robert Boyle, by means of his receiver and pump, made fundamental experiments to show that the light from all three sources, as well as that of the glow-worm, is dependent on a plentiful supply of air, and drew an interesting comparison between the light of the luminous wood and a glowing coal. Of course, Boyle knew nothing of oxygen, the essential factor in his experiments. Some material is oxidised; its nature and the production of the light which accompanies oxidation are the two fundamental problems in bio-luminescence. At least 36 orders of the animal kingdom contain one or more forms that produce light; in the plant kingdom only two groups contain luminous forms—some of the bacteria and some fungi, especially certain mushrooms—either the mycelium alone or the fruiting body alone, or both, are luminescent. Amongst animals, noctiluca, jelly-fish, ctenophores, sea-pens, some marine worms, various crustaceans, brittle stars, fire-flies and their larvæ, and glow-worms, a few molluscs—e.g., *Pholas* and *Pyrosoma*—and some fishes. All these are either marine or terrestrial; no examples of fresh-water luminous organisms are known. Most marine forms are deep-sea animals, some of them—fishes with complicated luminous organs, and many luminous marine animals—are surface forms of the plankton. The eggs of the *Lampyris* beetle emit light, even within the ovary. The only safe way to detect luminous organisms in sea-water is to add a little ammonia to the water, which slowly kills the organisms and causes any luminous forms to glow with a steady, continuous light for a time, a condition accompanying the death of the animal, a sort of "death-glow," to be compared, perhaps, with rigor mortis in muscle tissue. Of course, many non-luminous forms and—before the days of antisepticisms—even human wounds were infected with luminous bacteria, so that such luminescence is purely secondary. The supposed luminous character of the eyes of the cat in the dark is purely a phenomenon due to reflection out of the eye again of light which has entered from some external source. The eye of any animal is quite invisible in absolute darkness, and the same applies to the so-called luminous moss *Schistostega*. Luminous bacteria are very sensitive to oxygen, and "bacterial lamps" have been prepared and photographs taken by Raphael Dubois and also by Molisch, but it "seems doubtful, to say the least, whether luminous bacteria can ever be used for illumination."

"Cold Light" and Oxidation.

The ordinary forms of light to which we are most accustomed—sunlight, electric light, gas-light—are in each case parallel phenomena with the high temperature of the sources—bodies in a state of incandescence, emitting radiant energy or flux of many different wave-lengths, heat-light, and actinic rays, as well as other varieties of rays. But many bodies give off light at low temperatures and when stimulated by some other means than heat. Such bodies are spoken of as luminescent by the Leipzig physicist, Wiedemann, and to this category belong all luminous animals. Luminescences are classified according to the means of exciting the light—thermo-, photo-, cathodo-, radio-, chemi-luminescence, and so forth. They are all examples of "cold light," light produced at temperatures far below those observed in incandescent solids. Organo-luminescence, or the light of luminous animals, is in no sense phosphorescence, being quite independent of previous illumination of the animal; indeed, strong light has a bactericidal action on these forms, similar to that with ordinary bacteria. The spectra of luminous animals are quite similar to those of chemi-luminescent reactions, and this is essentially an oxy-luminescence, since oxygen is necessary for the reaction. All luminous animals require oxygen for light production, so that bio-luminescence and chemi-luminescence are similar phenomena, and the light of luminous animals is due to the oxidation of some substance produced in certain of their cells.

Physical Characteristics of Animal Light.

The characteristics of the physical nature of animal light—quality, efficiency, and intensity—have only been accurately measured in one group—the beetles. Very few organisms produce light to the fully light-adapted eye, although their light may seem quite bright to the dark-adapted eye, but the dark-adapted eye is a poor judge of the quality—i.e., the colour of a light—due to the Purkinje phenomenon, for "all cats are grey in the dark." Different luminous animals produce light of quite different colours as judged by our eye, and some animals possess several luminous organs emitting different colours—some two, some three colours—but this difference of the light does not necessarily indicate difference in spectral composition, because of the Purkinje effect. Examination of the spectrum of various luminous forms clearly indicates, however, that the different colours are really due to light rays of different wave-length, and are not the result of any subjective phenomenon. The spectrum of luminous animals never extends to the limits of the visible spectrum in either the red or violet, although it is possible that bands occur in the infra-red or ultra-violet; the radiation from the fire-fly is 100 per cent. efficient; it is a "cold light"; its energy is all light and no heat. The most efficient artificial illuminant has only about 4 per cent. of the luminous efficiency of the fire-fly. Luminous bacteria glow with less intensity than any other organism, and A. Lode calculated that the dome of St. Peter's at Rome, if covered with bacteria, would give little more light than a common stearine candle, so that luminous bacteria are not likely to come into vogue for purposes of illumination. Light from animal sources in no way differs from ordinary light except in intensity and spectral extent. It is all visible light, with no infra-red or ultra-violet radiation or rays capable of penetrating opaque objects. It may be polarised, can cause fluorescence or phosphorescence of substances, affect a photographic plate, cause heliotropism of seedlings, and stimulate the formation of chlorophyll.

Luminous Organs.

As to the luminous organs themselves, in one class the oxidisable material is formed and burned within the cell—intracellular luminescence; in the other the material is secreted to the exterior and is burned outside—extracellular luminescence. Some animals have very complicated luminous organs—in which chemical energy is converted into radiant energy—the lantern of the fire-fly and other animals is an organ of chemi-photo changes, while eyes which receive light are organs of photo-chemical changes. In some organisms the oxidation of luminous material goes on continuously independent of any stimulation of the organism—e.g., bacteria, fungi, and a few fish—or is intermittent, oxidation and luminescence occurring only as a result of stimulating which may occur from within (e.g., from nerves) or without. The flashing excited by stimulation has a varied rhythm in different animals, and different species of fire-fly can be distinguished by the character of their flashing. Some forms produce light only at certain seasons of the year, and some have a periodicity of luminescence—e.g., at night—failing to respond during the day. The photogenic material is formed within the cells or in glands, and in some forms is associated with granules in the protoplasm. As to the chemistry of light-production R. Dubois experimented with *Pyrophorus* and *Pholas* and Newton Harvey with other forms, including a *Cypridinia*, an ostracod crustacean.

---

[1] The Nature of Animal Light. By E. Newton Harvey, Ph.D., Professor of Physiology, Princeton University. Monographs on Experimental Biology. London and Philadelphia: J. B. Lippincott Company. 1920.

Luciferine and Luciferase.

The net result is that luminescence in these three forms is definitely shown to be due to the interaction of two easily separable substances, luciferin and luciferase, in presence of water and oxygen; but luciferin and luciferase from different luminous animals have different properties, and are to be distinguished by prefixing the generic name of the animal from which they are obtained. Luciferase has protein properties, is capable of oxidising large quantities of luciferin, behaves in many ways as a ferment, and may be so regarded. One of the most remarkable things concerning luminescence in general is the small amount of material necessary to cause a visible emission of light. A flash of light resulting from the impact on ZnS of a single α particle, a helium atom, is visible to the naked eye. Luciferin and luciferase from *Cypridinia* will also luminesce in exceedingly small concentration. One part of luciferase in 1,700,000,000 parts of water will give light when luciferin is added, and a similar dilution of luciferin will give light when luciferase is added; so great is the sensitivity of our eye in the detection of a small energy change. Luciferase seems to act as an organic catalyst, oxidising luciferin with light production; the reaction begins with an extraordinarily low oxygen tension, increasing in intensity with the increase of that oxygen tension, but very soon a maximum luminescence is obtained, and further increase of oxygen-tension gives no brighter light; the oxygen-tension curve is very similar to the hæmoglobin-saturation oxygen-tension curve. For a given mixture of luciferin and luciferase of *Cypridinia* the light becomes more intense, with increasing temperature up to a definite optimum, and then diminishes in intensity. A minimum, optimum, and maximum temperature for luminescence is observed in all luminous organisms. Luminous bacteria will still light at −11·5° C., nor is the power of luminescence destroyed by exposure to liquid air. The intensity of luminescence seems to be dependent on the velocity of oxidation of luciferin, and perhaps also on the particular manner in which luciferin is oxidised. We may assume as a tentative hypothesis that luminescence only occurs during oxidation (addition of O or removal of H) of the luciferin-luciferase compound.

PUBLIC HEALTH IN EGYPT.

Lower Egypt, 1918.[1]

THE Annual Return of Births, Deaths, and Infectious Diseases in Egypt during 1918, issued by the Statistical Department of the Ministry of Finance, has already been noticed in these pages (THE LANCET, August 7th, 1920, p. 331). The Report of the Public Health Department has now been issued, and contains much additional matter of interest; it relates to the calendar year 1918, with the exception of financial details, which refer to the financial year, ending March 31st, 1919. The population of the whole country, calculated for July 1st, 1918, is now stated as 12,820,900, as compared with 12,662,700 in the year preceding. The general birth-rate was 39·5 per 1000, as compared with 40·6 in 1917; the death-rate was 39·9, compared with 29·7. Ismailia, on the Suez Canal, had high birth and death-rates (88·0 and 624·1), owing to the presence of a large temporary population, both civil and military, whose births and deaths were calculated against the normal civil population. In the sparsely populated province of Sinai there was also a high birth-rate (51·1) and death-rate (795·4), for the same reason. The Eastern Desert Province had 3·7 births and 9·7 deaths per 1000. With these exceptions the birth ratios ranged from 31·5 at Aswân and 33·8 at Suez to 42·9 in the Fayûm and 44·9 at Asyût; in Cairo and Alexandria (the two largest cities) the ratios were nearly the same (36·9 and 36·7). Influenza made its first appearance in the country at *Alexandria in May, having* been imported from Europe by sea. In June it was recognised at Port Said, at Cairo in July, and in August in the province of Daqahliya, in the east of the Delta. Scattered outbreaks with a high rate of pulmonary complication and high death-rates occurred in other provinces, both of Lower and Upper Egypt in September, and in October it spread quickly over the whole country, with much pulmonary complication and corresponding high fatality. It reached its zenith in the first week of December. "The disease was certainly introduced from Europe by sea," and was prevalent in the British Army both in Egypt and Palestine before extending to the civil population. "The great majority of the 4059 towns and villages of Egypt were attacked," the spread of the disease being promoted by the frequent fairs held in the country villages and by military movements, but not by the Mecca pilgrimage. The total number of cases is not known, but the excess of deaths from September to December inclusive over the average of that period for 1916 and 1917, amounting to 138,648, may be presumed as roughly the total number of deaths due to this disease. Circulars as to personal precautions and immediate preventive measures were widely distributed, medical aid was organised, funeral celebrations stopped, and numerous special influenza hospitals opened in the districts most affected. In the treatment of cases with pulmonary complication cacodylate of guaiacol is considered to have given the best results. There were increases in relapsing and typhus fever notifications, but many of these were really cases of influenza. There were 357 "declared cases" of plague (with a fatality of 42·8 per cent.), compared with 732 cases in 1917, and 1702 in 1916. Owing to the invasion of Palestine in 1917 Egyptian troops and labourers were exposed to cholera infection, and several cases were detected in December of that year among men returning to Egypt. Five days quarantine and disinfection were imposed on all Egyptian levies at Kantara and Port Said before entering Egypt. Of 280,044 men so returning to the country 96·9 per cent. were kept under observation; prisoners of war were segregated, and instruction given in preventive measures, with practical training, at various centres throughout the country. The result was that no cholera was introduced into Egypt, which means that, in all probability, Europe was saved from a visitation of this pestilence.

Full and precise details are given of the work carried on in the Public Health Laboratories, the Vaccine and the Antirabic Institutes, showing that the Egyptian administration fully recognises the great value of scientific preventive medicine, and appreciates the material benefit to the country and its inhabitants derived therefrom. Colonel Cathcart Garner, Director-General of the Department, is to be congratulated on the results recorded. The immense advance in the public health (and the prosperity) of Egypt can perhaps only be fully appreciated by those of an older generation whose knowledge of the country dates back to the early eighties of last century.

Sudan, 1914–19.

In a report on the affairs of the Sudan, covering the years 1914–19, the Governor-General, Major-General Sir Lee Stack, makes several references to medical matters. He says that in 1915 a reorganisation of the medical work of the Sudan was carried out with the creation, under its own director, of an independent civil medical department, which had previously been under the control of the Principal Medical Officer, Egyptian Army. A new system of regulation of births and deaths has been instituted, which has resulted in a considerable increase in the number of registrations, as shown by the following figures:—

	1914.	*1915.*	*1916.*	*1917.*	*1918.*
Births	16,645	12,318	15,303	14,078	18,935
Deaths	12,450	16,065	9,587	9,172	14,452

These figures do not approach completeness or accuracy, as appears from the fact that the estimates of population from other sources give a total of over 4,000,000, as against 3,400,000 in 1914; but the system of registration does not obtain at all in the Southern Sudan. Seven outbreaks of cerebro-spinal fever occurred in 1914–15 with a heavy mortality. As regards small-pox, the Northern Sudan is fairly efficiently protected by vaccination. Small outbreaks occurred in Khartoum and Omdurman in 1917, but were soon controlled. Vaccinating tours arranged as far as possible during the winter months, but have had to be curtailed owing to shortage of staff. Considerable success has recently been obtained in vaccinating among nomad Arabs, who had previously been strongly opposed to it.

In 1918 the Sleeping Sickness Commission was considered to have completed the duties for which it was appointed, and its advisory functions were taken over by the Central Sanitary Board, the executive work being continued by the Principal Medical Officer of the Egyptian Army. In the Yei River district of the Mongalla Province about 175 patients, who had been three years from symptoms, were discharged as cured. In the last year progress has been made in the infected areas dealt with, and no new areas of human trypanosomi infection have been discovered. The P.M.O. of the Egyptian Army has forwarded the reports of Captains Spence and Simpson, R.A.M.C., on their several districts, and pays a deserved tribute to the patient steady work which these two officers and their Egyptian and Syrian staff are doing. The influenza epidemic made its appearance in the Sudan in September, 1918. It became very general throughout the Sudan, with a considerable mortality. The district which suffered the most appears to have been Berber province, north of Khartoum.

---

[1] Annual Report of the Department of Public Health, Cairo; Government Press, 1920.

It reached its most virulent stage in February, 1919, and died away in April and May. It is not possible to give more than an approximate estimate of the extent of the outbreak and consequent mortality. The senior M.O., Kassala, estimated 1600 cases out of a population of 6000 in Gedaref alone; 35 deaths from the disease were notified. The death-rate of all cases admitted to hospital was about 6 per cent. Malaria on the whole was not severe, except at Makwar, in the Sennar province, where the Blue Nile dam is to be constructed. Much work is being done in continuing the antimony treatment of bilharzia, first fully investigated and developed by Dr. J. B. Christopherson, the Director of the Khartoum and Omdurman Civil Hospitals. This officer, who has done valuable work for many years, retired on pension in May, 1919.

Dr. E. S. Crispin, the Director of the Medical Department, reports that considerable difficulty is still experienced in respect of both staff and hospital requirements. Advertisements for medical inspectors produced few replies and there has been a similar difficulty in obtaining Syrian and Egyptian staff. Funds were provided this year for a maternity school. The buildings are being constructed.

THE "BEE WORLD."

BEEKEEPERS will be interested in the *Bee World*, an international journal "devoted to the progressive interests of modern bee culture" (Apis Club, Port Hill House, Benson, Oxon). The 1920 June-September number contains much evidence of the enthusiastic support given to the journal by those who labour in this exacting industry, and includes an interesting article on the re-stocking with bees of the devastated areas of France and Belgium by the War Victims' Relief Mission of the English and American Society of Friends.

THE GIRLS' SCHOOL YEAR-BOOK.

THE official organ of reference of the Association of Head Mistresses, in its fifteenth annual edition (1920-1921), besides an alphabetical list of schools with the names of governing bodies and staffs, contains all details of fees, school courses, hours of attendance, and so forth, and indicates the various professional and business openings available for girls after leaving school. The articles on medical education for women, and on dentistry, pharmacy, nursing, massage, health visitors, sanitary inspectors, and the like, though short, are explicitly written and are of practical use to parents, guardians, and pupils. Lists of scholarships gained by women during 1919 and university honour degrees, 1919, are among the other contents of this useful book of reference, which is published by the Year-Book Press, 13, Museum-street, London, W.C. 1, price 7*s*. 6*d*.

A RADIANT HEAT CONSERVER.

IT is estimated that some 30 per cent. of the radiant energy of a fire is directed to the floor in front of that fire, where its heat is taken up by the floor-door draught. Mr. C. Wray, F.R.C.S. Eng., has invented a device whereby this difficulty may be overcome, consisting of a horizontal brass tray on telescopic legs with vertical wings on the right and left borders, so arranged that they can be adjusted to different widths of fire. The general effect is practically to bring the fire 18 inches forward into the room; as heat diminishes as the square of the distance the advantage of this fact is obvious. The right wing reflects heat to the left of the room, the left wing to the right of the room; the two combined protect the incandescence from draught. When this heater is used with a good gas-stove there is no occasion to light the fire more than three minutes before making use of a room. A kettle or an entire meal can be kept at boiling point, and the heater proves ideal for toasting purposes; it is also useful for rapid drying of instruments and clothes. It is manufactured by Messrs. Gowlland, Morland-road, Croydon.

"HOW TO LIVE FOR MORE THAN ONE HUNDRED YEARS."

Mr. L. H. Goizet, the author of "Never Grow Old" (London and New York: G. P. Putnam's Sons. 1920. Pp. 191. 10*s*.) states that "chemistry teaches us that the composition of the organised being reduces itself to four gases, azote, oxygen, hydrogen, and carbon, and to a few mineral principles of earthly origin. Since the gases are elastic—that is, able to be compressed or dilated—the form (of the body) must be likewise." If the gases are not "maintained in a sufficient state of cohesion and compression by the universal rotatory movement" they dilate, "and the separation of the form commences, to be continued more or less rapidly in a complete way to total anishing," which lamentable result can be postponed for a ng time by the author's system of superficial tractile atory rubbings beginning "at the centre of gravity of the n which corresponds exteriorly to the crown of the d." It is difficult to understand how such nonsense e to be printed.

MEDICAL PRACTICE BY FOREIGNERS IN SPAIN.

THE position of foreigners who desire to practise medicine in Spain has long been obscure, and we are glad to be able to give categoric information on certain points, thanks to the courtesy of the Registrar of the General Medical Council. All foreign subjects, it appears, may carry on their respective professions in Spain, except such callings as imply the use of authority or jurisdiction, provided that they have studied and been approved like a Spaniard in official Spanish educational establishments. Actual medical reciprocity only exists with some American Republics, and with Portugal, but foreigners who prove the validity of their qualifications and have practised for six years are admitted, the right of refusing recognition being reserved.

In a specific case the following information was supplied: The candidate must present an academic certificate, giving details of all courses of study, which must be issued by the head of the University or other authority under whom the studies were carried on. This must be authenticated by the Minister of Education, and his signature must be verified by the Foreign Minister in England. This in its turn must be authenticated by the Minister for Foreign Affairs in Madrid. The application must then be reported upon by the College of Medicine and the Council for Public Instruction in Spain. This information will be incorporated in a new edition of the pamphlet on the conditions of practice abroad, shortly to be issued by the General Medical Council.

YEAR BOOK OF PHARMACY.

THE 1920 volume (London: J. and A. Churchill. Pp. 594) contains the usual abstracts of papers relating to pharmacy, materia medica, and chemistry, contributed to British and foreign journals during the year ending June 30th last. This part has been well done by Mr. J. O. Braithwaite. The list of new remedies and of new applications of old remedies is compiled by Mr. Thos. Stephenson, F.R.S. Edin. A novel and useful feature is a "research list" or enumeration of subjects suggested for research, for which grants may be made by the British Pharmaceutical Conference. Finally, the transactions of the Conference held at Liverpool last July are given in full, including Mr. C. A. Hill's valuable address on Progress in Science and Pharmacy, comment upon which appeared at the time in our columns.

THE LANCET, JANUARY 8, 1921.

An Address
ON
THE USE AND MISUSE OF THE CURETTE.

Delivered to Graduates at the Manchester Royal Infirmary on Nov. 9th, 1920,

BY W. E. FOTHERGILL, M.A., B.Sc., M.D. EDIN.,
PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY OF MANCHESTER.

THERE has recently been a strong reaction against the indiscriminate use of the curette; but from the first some authorities strictly defined the indications for scraping away the endometrium. Thus Marion Sims appears to have introduced the sharp curette about the year 1865, and soon afterwards T. A. Emmet wrote: "As regards the instrument of Dr. Sims, I honestly believe that the ingenuity of man has never devised one capable of doing more injury." Ever since that time the curette has had its detractors; but in spite of them all it has gained a popularity probably unrivalled by that of any other surgical implement. It may interest and possibly amuse you to hear some recent expressions of opinion on this subject. J. O. Polak says: "It seems almost impossible to educate the profession to the acceptance of the fact that the curette has but two well-defined indications: first, to remove the products of conception before the eighth week; and, second, to make the diagnosis in inter-menstrual uterine bleeding at or after the menopause."

A. Heineberg[1] thinks that "despite all that has been written and taught in the last few years about the futility or harmfulness of uterine curettage, there is probably no operation which is still so frequently abused." This writer describes the now well-known changes which occur during the menstrual cycle. Only 2 or 3 mm. in thickness during the resting phase, the endometrium grows to 6 or 7 mm. thick during the *pre-menstrual* phase. There is loss of superficial epithelium and destruction of the stroma by extravasation of blood during the menstrual phase, and the process of repair which begins before the bleeding ceases reproduces a new endometrium 2 or 3 mm. thick by the beginning of the next resting phase. These changes, the writer reiterates, account for the varieties of so-called endometritis described by our predecessors; and he emphasises the futility of scraping away the endometrium because it varies from phase to phase of the menstrual cycle. Heineberg next expresses with satisfaction his belief that curetting is being done less and less in incomplete abortion and in puerperal infection. He goes on to condemn the operation in dysmenorrhœa because it is only successful in odd cases, and then it is the preliminary divulsion of the cervix that does good, not the curetting. In sterility he says that many uteri are infantile and unfit for pregnancy, and that lack of offspring can be demonstrated to be the fault of the male in from 30 to 40 per cent. of cases carefully studied. He mentions 100 cases re-operated by Polak, amongst whom were 43 who had been curetted for sterility, although they were the victims of old pelvic infection. Of the 43 women, 39 had been curetted without first having their husbands examined. Howard A. Kelly's figures are quoted to show that less than 15 per cent. of curettings for sterility are followed by pregnancy. The work of A. H. Curtis is next cited to prove that the endometrium is generally germ-free, and this is regarded as an objection to curetting because during the operation the uterine cavity may be infected. This writer next condemns the use of the curette for leucorrhœa, and finally he says that, "the statistics of T. S. Cullen, C. C. Norris, and R. M. Rawls, combined with the work of Curtis, present a strong condemnation of that pernicious and thoughtless practice which includes curettage as a routine measure in most (vaginal) operations on the pelvic viscera."

Indiscriminate Curettage.

W. A. Lincoln[2] writes that the most accepted of all rules of conduct is "When in doubt, curette." He, like Heineberg, mentions that the old varieties of so-called endometritis are nothing but normal phases of the menstrual cycle, and that, naturally, one or other of them was found whenever a scraping was examined. "A nice symptomatology was built up around these, all the way from amenorrhœa, dysmenorrhœa, metrorrhagia, menorrhagia, or any other kind of discharge to general symptoms of lassitude, headache, backache, or any other ache." "In case some women might be left out it was stated that endometritis might be present without any symptoms whatever. Given a curette and a woman, the old-time gynæcologist would always find endometritis." Lincoln quotes Cullen to the effect that endometritis is a very rare disease and H. B. Whitehead to show that hæmorrhage is not a symptom of it. He cites Busse as to the result of curetting for hæmorrhage in 500 cases with benefit in only 10 per cent. of them. Passing on to the dangers of curetting, he says that in puerperal infection many deaths have been laid to its door, and refers to A. P. Heineck's 160 cases of perforation of the uterine wall, and Schweetzer's[3] 105 German cases with a death-rate of 25 per cent.

To secure personal information Lincoln wrote to a number of his neighbours and received from 24 medical men 43 curetting disasters with 11 deaths, a mortality of 25 per cent. He publishes all these cases in detail. There were 5 cases of severe bleeding with 3 deaths; 8 cases of sepsis with 3 deaths; 27 cases of rupture of the uterus with 4 deaths; and 3 cases during early pregnancy with 1 death. He concludes: "A curettage is a major operation not to be undertaken except under the very best conditions, and with every possible precaution, by a careful and skilful surgeon." J. W. Bovée[4] writes: "It is a notorious fact that the most slovenly and ignorant physician resorts without hesitation to the curette for various diseases of the uterus, real or otherwise." He condemns the routine curettage incident to pelvic plastic surgery, and in so-called endometritis. Incomplete abortion he calls a discarded or discredited indication, the curette being "not only very hazardous but decidedly unnecessary except in case of very dangerous hæmorrhage." Subinvolution as an indication is also discarded. A chapter of accidents follows, including "resection of 70 inches of intestine after perforation of the uterus with the curette," "perforation of the puerperal uterus," and "17 centimetres of gut drawn out of the uterine cavity." This writer also quotes the work of Curtis to show that the uterine cavity is generally sterile, the idea being that it is a very risky performance to pass an instrument through the cervical canal, which is sometimes infected, into the uterine cavity, which is generally germ-free.

Proved Uses of the Curette.

Between them the authorities just quoted condemn most of the usual indications for the use of the curette, and if they are all right it follows that curetting is generally wrong. We are all ready to admit that there is still much futile curetting; but the pendulum has swung too far against a useful instrument, and it is worth while to consider the moot points seriatim in the cold light of common-sense and experience.

Acute septic endometritis.—Take first the question as to the use of a large curette for emptying and cleaning the uterus infected either post-partum or post-abortum. If this is done before the pathogenic organisms have entered the blood stream the result is generally excellent. The cleansing of the uterine cavity should, of course, be completed with fairly dry swabs, and not by intra-uterine douching, which sometimes forces septic material and irritating antiseptic solutions up through the tubes into the peritoneal cavity with disastrous results. The dry cleaning should not be repeated, and no subsequent intra-uterine or vaginal douche is desirable. Once emptied and swabbed, not swilled, with an efficient concentrated antiseptic, the uterus is best left alone. Now if the patient already has septicæmia before the curetting is done she may, of course, subsequently die of septicæmia; but there is no reason for joining Lincoln in laying her death at the door of the curette, which in septicæmia does no harm if it does no good.

[4] Bovée: Surg., Gyn., and Obstet., June, 1920, p. 618.

Incomplete abortion.—The discovery of retained products of conception and their removal from the uterus remain, in spite of all that has been said to the contrary, sound and common uses for the curette. And these include subinvolution, in which the removal of an unduly persistent layer of decidual tissue is often an essential step in the treatment.

Hæmorrhage.—It is clear that removing the endometrium will not cure so-called functional uterine bleeding; in other words, bleeding which is not due to any local lesion, but is menorrhagia due to excess of ovarian secretion, anæmia, or some other general cause. But the dilator and the curette are essential for the discovery of mucous and small fibroid polypi, of malignant disease within the cervical canal and uterine cavity, and of the results of infection superadded to post-menopause changes known as "senile hæmorrhagic endometritis." Except in malignant cases, they provide the treatment as well as the diagnosis. The rule should be, curette in metrorrhagia but not in menorrhagia. Neither the cause of menstruation nor the cause of excessive menstruation is local.

Preliminary to plastic vaginal operations.—The use of the curette as a preliminary step in operations for genital prolapse has been utterly condemned. But when the cervix is to be amputated or repaired it must first be dilated in order to gain working room for suturing. Again, it is wise to make sure that all is well within the uterus before so narrowing the vagina as to render access to the uterine cavity very difficult thereafter. Polypi are often found and removed during the preliminary scraping, and early malignant disease of the body of the uterus is discovered from time to time. This has happened in cases of my own, three times within the last few months, and has confirmed me in the habit of curetting before operating for prolapse. The prognosis in cancer of the body is something like ten times as good as in cancer of the cervix; and, in early cases, hysterectomy seldom fails to save the patient. If I had omitted the routine preliminary curetting, these three women would have gone away cured of prolapse only to return in a few months with cancer of the uterus advanced beyond remedy.

Leucorrhœa.—Let us grant at once that it is ridiculous to curette for "the whites"—namely, creamy leucorrhœa or excess of the normal vaginal discharge which does not come from the uterus at all. In slimy leucorrhœa, again, the mucus appears to come mainly from the cervix and scraping does not much help matters.

Sterility.—Let us also grant that it is quite wrong to curette for sterility, without first making sure that there is no definite cause for it either in the patient or her husband. The operation is useless for this purpose in cases of relative sterility (one child or one abortion). It is also necessary to remember that age, pure and simple, is the commonest explanation of sterility and that when a woman aged 40 marries, the odds against her becoming pregnant is about 100 to 1. But when both husband and wife are sound and young, and have been married three or four years without offspring, experience shows that conception quickly follows curetting in a certain percentage of cases. Whether the dilator or the curette efficient instrument in these cases remains to be

norrhœa.—Here the trouble is that spasmodic gestive dysmenorrhœa are constantly confused. wisting pain dating from puberty and limited hours on the first day of the period is often cured by the birth of the first child and is often relieved by thorough dilatation of the cervix under an anæsthetic. It is useless to dilate a cervix through which a child's head has already passed without curing the pain. On the other hand, neither the dilator nor the curette can remedy the dull aching of distended veins in the pelvis any more than they can relieve the aching of varicose veins in the leg or in the scrotum. Thus the curette is out of court for dull aching pain either during or between the menstrual periods. Such pain is not in the uterus nor is it caused by it. If a patient has both spasmodic and congestive dysmenorrhœa it is worth while to dilate; for the sharp pain of the first day may be relieved though the dull premenstrual and menstrual aching will remain.

Dangers of Curettage.

There is nothing to be gained by exaggerating the risks of dilatation and curetting—namely, infection, splitting the cervix, and perforating the body of the uterus. Infection can be avoided by the usual precautions. If the operator retains in his own hand one of the vulsellæ with which the uterus is drawn down during dilatation, his own muscular sense will estimate the force he is exerting upon the dilator in his other hand. Thus he should avoid the risk of causing serious laceration of the cervix. It is much easier to perforate the uterus with a small dilator than with a large one. Therefore it is wise to push in the smaller dilators only 2½ inches and to refrain from attempting to measure the uterine cavity until the internal os will admit the passage of a large dilator. The length of the cavity once estimated, the operator is not likely to perforate or tear the uterus with the curette. Clean perforation of a healthy uterine wall does no harm, as the uterine muscle closes the hole at once. But if the organ is so atrophied or degenerated that it tears easily it should be removed at once.

Summary and Conclusion.

To sum up, the broad fact remains that the curette is mainly a diagnostic instrument. Apart from mere increase in the duration or quantity of the menstrual flow, and in the presence of any uterine hæmorrhage whose cause is not clear, the rule, "When in doubt, curette," is a sound one.

In women of reproductive age the cause of irregular bleeding is found in the majority of cases to be retained products of conception; and it is remarkable how often these relics are found in women who will not admit that they have missed a single period. Sometimes one or more polypi are found. Occasionally, though the cervix feels normal, the curette finds a place within the cervical canal where epithelioma yields like cheese. And not so very rarely malignant disease is found within the body of the uterus. After the close of reproductive life uterine bleeding absolutely demands dilatation and exploration by curette unless the hæmorrhage has an obvious cause, such as cancer of the cervix, the twisting of the pedicle of an ovarian cyst, or the degeneration of a fibroid. In these post-menopause cases exploration generally reveals the presence of cancer of the body of the uterus; but sometimes there is nothing but the result of a chronic infection whose steps are senile vulvitis, vaginitis, cervicitis, endometritis. In these cases, if the cervical canal becomes occluded after the endometrium has been infected, the result is pyometra, with distension of the uterus by pus and blood-stained purulent vaginal discharge. Now, in cancer of the corpus uteri infection of the ulcerated new growth occurs very late, so that the discharge becomes offensive only when the disease is far advanced. Thus foul discharge means pyometra or late cancer of the body, while a discharge of pure blood through a clean vagina means early cancer of the body. The cases of senile hæmorrhagic endometritis and of pyometra are more numerous than we realise, and they are quite curable by the curette. Thus the operator who removes every enlarged bleeding uterus in an old patient without preliminary exploration will subject to the discomforts and risks of hysterectomy a certain proportion of old ladies who could have been cured by a simpler and safer method.

A Dissertation

UPON

CARBUNCLES.[1]

BY SIDNEY PHILLIPS, M.D. LOND., F.R.C.P. LOND.,

CONSULTING PHYSICIAN, ST. MARY'S AND THE LONDON FEVER HOSPITALS; PHYSICIAN, LOCK HOSPITAL.

Differing Definitions.

SOME authorities regard a carbuncle as an affection of the skin only; in H. N. Barnett's "Students' Handbook of Surgery" it is defined as "an acute phlegmonous inflammation of the skin with multiple openings, induration, sloughing of subjacent tissues and of the skin." Others admit that the subcutaneous tissue is also affected. H. W. Stelwagon[2] writes of it as "an acute, usually egg- to palm-sized, more or less circumscribed flattened phlegmonous inflammation of the skin and subcutaneous tissues terminating in slough." Watson Cheyne and F. F. Burghard[3] define it as "a gangrenous inflammation of the skin and subcutaneous tissues affecting a considerable area." Others do not regard it as a skin affection. Marcus Beck[4] calls it "a spreading inflammation of the subcutaneous areolar tissue implicating the skin and terminating in death of the affected tissues with formation of slough." W. Rose and A. Carless[5] attribute carbuncle to the subcutaneous tissue.

It will be seen that some authors regard carbuncle as an affection of skin only, others as an affection of skin and subcutaneous tissue, whilst others again do not admit that the skin is involved at all. The derivation of the word from *carbo*, a coal, apparently from the fancied resemblance of the surface appearance to that of a living coal, gives no justification for limiting the lesion to the structure of the skin. As a fact the microbic organism to which the affection is due makes no distinction between anatomical divisions, but impartially invades any tissue. Carbuncles begin on the surface of the skin, as seen in pustules, or in the deep layers of the skin, or in the tissue beneath the skin, and even under deep fascia. All carbuncles attempt, and most succeed, in destroying the skin, but this does not constitute them as a skin disease. J. E. Erichsen remarks, "whether carbuncle commences in the skin or in the subcutaneous areolar tissue is not definitely ascertained." But I think the answer to the question is that it may begin in either.

Probable Sequence of Events in Carbuncles.

Opinions also differ as to whether a carbuncle is an inflammatory process. Most of the authors I have quoted, with J. F. Schamberg,[6] J. H. Sequeira,[7] and others, regard it as a phlegmonous or gangrenous (Cheyne) inflammation, terminating in slough. Others are more guarded; thus Malcolm Morris[8] terms it an "infiltration," and Pye-Smith[9] speaks of it as the "inflammation which accompanies sloughing." A. von Winiwarter,[10] however, states that it is primarily a tissue necrosis, and Rose and Carless[11] describe it concisely as "an extensive gangrene of the subcutaneous tissues, due to a local invasion of pyogenic microbes." Inflammation ordinarily leads to suppuration, diffuse or local, but the pathognomonic sign of carbuncle is sloughing or necrosis of tissue. A carbuncle begins in a more or less acute sudden pain; after a varying interval neighbouring tissues become tense and sooner or later the surface of the skin shows signs of inflammation and œdema. Eventually the skin is ulcerated through from below; as soon as this is accomplished the inflammatory symptoms begin to subside, and the redness, heat, and swelling fade away.

I think the sequence of events in carbuncles makes it probable that necrosis of tissue is the first event and that the inflammatory process is secondary, being the natural method of separation of the slough from the living tissues and eliminating it from the body, much as happens in gangrene in other parts. It is of interest to remember that carbuncle is apt to occur in diabetics, who are specially prone to gangrene. And, with slight modification, I shall adopt as my definition of a carbuncle that of Rose and Carless, that it is a gangrene of deep skin or deeper tissues due to a local invasion of pyogenic microbes.

Cause of Sloughing.

A. von Winiwarter suggests that the sloughing is due to early thrombosis of vessels due to microbic invasion. And M. Kaposi[12] writes: "Some believe, though it has never been proved, that thrombosis of vessels is the first event." The suddenness of the pain that sometimes occurs supports this belief, and the theory of primary thrombosis, resulting in necrosis of tissue and consequent inflammatory effusion, seems to me the most probable explanation of the formation of carbuncle.

Pathology of Carbuncles.

Ætiology.—The proximate cause is generally, possibly always, the *Staphylococcus pyogenes aureus*. Entry into the body: I believe it is generally held that a carbuncle results from local infection of skin, staphylococci already existing there suddenly taking on activity in debilitated persons. This is no doubt true in many cases, but there are difficulties in believing that it is always so. It is not easily credited that the staphylococcus can, so suddenly as it does, set up a fierce acute carbuncle from a supposed local infection merely because the host is debilitated. Carbuncles sometimes occur in non-debilitated persons, and carbuncles occurring in long series at parts of the body distant from one another can hardly be said each to arise from local infection. Having once invaded the body in a pathogenic form, the organism may remain in some local focus—perhaps the scar of the carbuncle—and set up fresh local lesions. Age: Usually after middle life, though in war conditions they occurred in early age, being quite a scourge in the English and French armies. Sex: Males many more than females. Locality: Mostly on dorsal surfaces of the body or scalp, but they may occur on the face, the worst carbuncle of all being that on the lip. *Constitutional conditions:* Debilitating conditions, exposure, fatigue, &c., as also diabetes, and (it is said) albuminuria. Diet: Carbuncles have been numerous since 1914 and have been attributed to deficient food. But mere starvation does not lead to carbuncles, and if the cause be deficiency or defect in some dietetic principle, we do not know what it is. It has been suggested that deficiency in fresh vegetables rendered it commoner amongst English and French than in the German army. Periodic frequency: Erichsen remarked 40 years ago that carbuncles are more numerous in some years than others, and they have been more common all over the world since 1914. All microbic affections are liable from time to time to take on virulence and wide distribution to which debilitating conditions and overcrowding contribute. Relapses: Carbuncles often occur in series, sometimes long continued through months or years, and are apt to recur after some months' interval.

Symptoms.

Pain.—The first symptom is pain—in superficial carbuncles mere burning, itching, or irritation, in deeper ones sometimes acute and lancinating like a stab with a knife or the sting of an insect, but there is nothing to confirm the theory that carbuncles commence in a sting. In very deep-seated lesions the pain may be deep and throbbing, perhaps intermitting for hours or even a day. Pain, especially in deep-seated carbuncles, may precede other symptoms for a long time. Usually in a few hours the skin gets red and hot, and an area of variable size gets vivid red or bluish with much hyperæsthesia and heat, and sometimes widespread surrounding œdema. When the process is very acute a vesicle or pustule may develop on the surface, which dies away and has nothing to do with subsequent openings in the skin resulting from ulceration from below. Pain, tension, and throbbing increase, and there results a tense, painful, prominent, bright-red oval swelling, with surrounding vivid œdematous and brawny tissue. Pus shows at points beneath the skin and ulcerates through it, this being accompanied by sharp pains.

[12] M. Kaposi: Diseases of Skin, p. 292.

The more vascular and superficial the carbuncle the sooner is the skin destroyed. Some carbuncles, even small ones, are much less acute—this form of "stodgy" carbuncle has a thick tough slough—there is very little pus, and what pus there is may be confined under the slough; the opening formed in the skin may take days to enlarge sufficiently to allow the tenacious slough to get freed. In carbuncles where the slough is very deep-seated the pain may be intense owing to the imprisonment of the inflammatory effusion beneath the tough unyielding superlying tissues. These carbuncles may fail to "point" at all, the pus running in any direction in the deep tissues.

As the openings in the skin enlarge or coalesce and débris of slough escapes, the pain, tension, and surrounding œdema subside, and the livid skin gradually returns to the normal. Where there have been many openings small separate cavities may ensue, but these soon fall into one, and a deep crater remains with granulating surface, which contracts and heals, leaving often a very small cicatrix; indeed, it is surprising how skin which seemed doomed to slough may entirely recover. But a carbuncle usually takes a week at least to open up, a fortnight to discharge all slough, and a week or more completely to heal; a month is the least time from beginning to end, and many take three months.

One cause of delayed healing is the existence in the tissues of tough fibrous strands of tissue which have not been destroyed by the necrotic process as have the softer tissues. They get tough and even woody, like the rootlets of weeds, and prevent final cicatrisation unless dissected out with knife or scissors.

It is said that carbuncles, unlike boils, spread at one part while healing at another. I think this only happens in that type of carbuncle which is an aggregate of several smaller foci which do not all begin simultaneously or develop equally rapidly.

Two Types of Carbuncles.

There are distinguishable two types of carbuncles: (1) The commoner and more superficial one, which develops mainly in numerous separate foci of necrosis, is very vascular, soon comes to the surface, perforating it by several openings, and has much pus and soft sloughs easily discharged in shreds or fragments; (2) a more deep-seated type with a single tough dense slough having much less vascularity and pus formation; the opening through the skin is formed and enlarged very slowly, and the slough is with difficulty eliminated, being tough and remaining whole instead of softening and breaking up.

In some individuals, especially alcoholics and elderly obese persons of small vitality, carbuncles show no tendency to heal, but continue spreading till a large flattish surface, perhaps as large as a plate, is produced and death occurs from asthenia. Lymphangitis and lymphadenitis are not very common with carbuncles, but the former may produce vivid redness and burning pain of the skin, and the latter may produce very tender enlarged glands. A very troublesome accompaniment of carbuncles is the development of secondary carbuncles near the main one, and of vesicles or pustules on the surface of the skin. The latter may develop and become purulent in a few minutes. They are intensely painful; the more profuse the suppuration, the more liable are they to occur; they seem to develop from the pus running over the skin: this pus, which may be very irritating, producing a scalding pain on the skin, is sometimes itself of strong acid reaction.

Constitutional Symptoms.

Many writers represent these as severe, and speak of fever, rigors, and patients finally sinking from exhaustion. Carbuncles usually occur in debilitated persons —sometimes in diabetics—but ordinarily there is little fever or constitutional disturbance, and the patient is able to get about and follow his occupation. In the early stage, before the skin has given way, there is much pain and a feeling of illness, and long series of carbuncles deteriorates the health by means of pain, sleeplessness, and loss of appetite. But, as a rule, general symptoms are slight in comparison with local symptoms, and severe constitutional symptoms are infrequent. In the grave case of spreading carbuncles the symptoms are passive rather than active, the patient gradually weakening till he dies.

Facial Carbuncles.

Carbuncles may occur on the face, having the same characters and course as elsewhere on the body. On the nose they sometimes create huge swelling and give great pain, but subside, leaving little trace. But there is a special form of facial carbuncle, sometimes called malignant carbuncle of the face, which N. Davies-Colley has thus described:—

> "It is generally seen between ages of 20 and 30. Beginning as an itchy pimple, usually upon the upper or lower lip, the swelling rapidly affects the whole lip, which is soon four or five times its natural size. It is brawny, livid, and very painful. Numerous pustules or vesicles form, especially on the red surface of the lip. The inflammation extends upwards towards the eye or downwards towards the clavicle; the eyeball may protrude; severe pyrexia with rigors occur; pain in the side, bloody sputa, and other indications of lung implication follow, and the patient may succumb to pyæmic phlebitis in a week from the onset. On section of the lip numerous small abscesses are found and not a homogeneous slough, as in true carbuncles."[13]

Sir James Paget writes that at one time he did not regard it a carbuncle, but subsequently came to the conclusion it was a carbuncle with peculiarities due to its position. It is distinguishable from anthrax, which it resembles, by bacteriological examination. Clinically "in malignant pustule the vesicles are close together and grouped in a ring round a central blackish slough; the swelling of malignant pustule is less painful and there is no suppuration."[14]

The affection is a very terrible one and is nearly always, if not always, hopeless, but a case is recorded by R. Coombe and R. V. Solly, of Exeter,[15] cured after injection of 50,000,000 staphylococci and two succeeding doses of 25,000,000 each, together with internal use of citric acid. The treatment advised is scraping away the affected tissues, applying carbolic acid, and ligaturing the facial vein.

Diagnosis.

Cheyne and Burghard say "a carbuncle is a number of boils aggregated together"; Pye-Smith that "a boil and a carbuncle are pathologically identical," and S. Milsome[16] writes, "a carbuncle consists of a number of boils grouped together." But a boil is an affection of the follicles of the skin, and a carbuncle may be very much more and does not necessarily affect the skin except secondarily. And though some carbuncles may be merely aggregated boils, others are very much more. Clinically a boil is said to be distinguishable from a carbuncle by its size, but a carbuncle may be very minute and a boil may be of a large size.

It is curious that many writers say boils are usually multiple and carbuncles single: Rose and Carless, H. N. Barrett, Schamberg, Sequeira, all give this as a diagnostic feature, and Erichsen mentions as a singular fact that he once saw a carbuncle followed by a dozen other ones. In any case such a criterion is useless in diagnosis, as it involves waiting to see if the lesion is multiplied, but boils may be solitary and carbuncles are very frequently multiple.

[15] R. Coombe and R. V. Solly: THE LANCET, 1909, vol. ii., p. 145.

[16] Clifford Allbutt's System of Medicine.

Another distinction has been made that the projection of a boil is oval or round or conical, while a carbuncle is flat. As a fact a carbuncle may form a projection the size of an orange. Multiple perforations are said to distinguish carbuncles from boils, but carbuncles may have only one opening.

Neither size nor prominence nor multiplicity will serve to differentiate boils from carbuncles, but when an affection localised to the hair follicle or sweat gland occurs it is a boil; if there are several of such lesions aggregated together a superficial carbuncle results; if the lesion extends deeper it is a carbuncle.

Prognosis.

Paget writes, "Carbuncles are looked on in the profession as dangerous things, but not in my experience." They are, however, still written of as "always a serious malady" (Stelwagon).

But, with the exception of the malignant facial carbuncle, I think it is the general experience that the prognosis is good both as regards the carbuncle and the patient. Even diabetics usually get well of carbuncle. But, as has already been said, in broken-down alcoholics or in elderly persons of small vitality death may occur from asthenia. And long successions of carbuncles through a series of years no doubt carry with them elements of danger.

Treatment.

Some advocate operation in all cases, but I will deal first with treatment without operation.

(*a*) Abortive treatment. Local subcutaneous injection of carbolic acid (1 in 20) may help to shrink up small localised carbuncles. (*b*) Plasters of resin or of lead with a circle cut out of the centre have been used, but can only restrain development of small carbuncles. (*c*) Painting with tincture of iodine or a strong chlorinated solution will dry up very small staphylococcal gatherings, but only when they are in the superficial skin. (*d*) Bier's treatment by cupping in the early stage is said to abort carbuncles. As a rule one has to take it that suppuration will occur, and treatment should be directed to relieving pain and to assisting the advance of inflammatory products through the skin. This is best effected by hot fomentations or poultices, preferably the latter, as they retain longer their warmth and moisture and the linseed oil of the meal is sedative to the skin. They must be changed frequently and must not be too hot, or they will scald the inflamed skin. As soon as possible after discharge occurs through the skin, fomentations should replace poultices; this cannot always be done directly discharge occurs, as some foci of suppuration may be later than others. A good plan is to alternate poultices and fomentations till the latter are used alone.

It is desirable to keep the skin as little moist and sodden as possible. But if discharge is very slight a dry dressing will cake and imprison the pus, giving much discomfort, and if the discharge is profuse, the dry dressing soon becomes a wet one. Dressings should be as small as possible; gauze absorbs discharge better than lint. A good plan is to put a large piece of dry lint between the skin and the fomentation with a central hole cut out of it over the central part of the carbuncle with its smaller gauze dressing. Painting the skin around the carbuncle with diluted tincture of iodine also lessens the infectivity, but must not be done so often as to inflame the skin, and it is well not to apply a hot fomentation immediately after painting with iodine tincture. I do not think antiseptic lotions are required before the skin is broken.

The antiseptic used should be non-irritating, used warm, gradually altered in strength or composition, and gaseous as well as liquid.

Antiseptic Applications.

Antiseptic applications should be avoided that irritate or inflame the skin when used continuously for a long period. Carbolic acid is an established application for carbuncles, but it numbs the skin even when used occasionally, and I do not think it is the best antiseptic for the long-continued use required for a carbuncle. Boric acid is very irritating to some skins, even used as boric lint. Flavine is non-irritating and I found it very useful, but it has the disadvantage of staining everything bright yellow. Chlorine and hypochlorites are time-honoured antiseptics. Lister found liquor chlori of the old Pharmacopœia (1870) effective when a 1 in 5 solution of phenol failed. The hypochlorites used to be employed, but of late eusol, which is the first preparation of the actual acid (of which it contains about 5 per cent.), has been used. The hypochlorites destroy bacteria, but do no serious damage to the phagocytic activity of the leucocytes or to the reparative power of the tissues.

But according to W. Martindale, eusol rapidly loses its antiseptic power if warmed, and must therefore be used cold. This is a disadvantage, as cold applications are not congenial to carbuncles; I also found eusol, after being on for some time, developed a marked burning power; when mixed with serum in exudation it probably undergoes chemical change. I prefer the liquor sodæ chlorinatæ in 1 in 20 or 1 in 30 solution; it is a non-irritant powerful antiseptic, and it has what I think is the advantage of emitting gaseous chlorine; I think antiseptics which are gaseous as well as liquid are indicated in local treatment of bacterial affections.

Long Continuance of Chemical Applications: Strapping.

An application, at first painless, gives pain and irritation after it has been used for a time; in the case of flavine, though it does not irritate, the dressings remain stained with it many days after it has ceased to be applied. Probably other chemicals are also absorbed by wound tissues after continuous application, and the hint may be taken that it is as well gradually to lessen their strength or to change the antiseptic employed. Strapping irritates the skin, but it is sometimes impossible to keep small dressings in situ without it, especially when the patient is up and about. I found Mead's less irritating than the white rubber oxide of zinc strapping.

Syringing; Cupping; Compressing.

Nothing is so effective in getting rid of debris of slough and pus from the recesses of a carbuncle as syringing, preferably with the same solution as is used for the dressings. Kaposi writes "removal of necrotic plugs before they are separate is absolutely useless." I think it is worse than useless; it is intensely painful and, if successful, leaves behind it a raw, absorbent surface; nor is any time gained by it, for if sloughs be allowed to separate spontaneously, by the time they do so the cavity will have shrunk to a small size, will be lined with granulations, and will rapidly close. Cupping is recommended for helping separation of slough, but syringing is quite sufficient and is essential. With reference to compression, I. B. Muirhead[17] has pointed out that if a carbuncle be squeezed, after a few minutes "the patient complains of creepy, sickly, or faint feelings, due obviously to a mild form of intoxication," showing that a poison in the carbuncle has been extruded into the system. I do not know if this explanation be correct, but I am sure that manipulation and compression of carbuncles at the dressings do produce a feeling of illness and should be done very gently; if the syringe is used it is not much required.

It is important to abstain from rubbing the skin with spirit or other soap, which seems to open up the follicles in the skin and is sure to be followed by a plentiful crop of staphylococcal pustules or secondary carbuncles. Too much of any form of washing of the skin is undesirable. Occasional warm water washing and drying with starch or zinc stearate powder is useful, but a long-powdered skin gets "itchy."

Ointments.

Ointments and greasy applications, even when they contain antiseptics such as calomel, favour development of secondary carbuncles and pustules. After a carbuncle has opened up glycerine of carbolic acid diluted six times may be applied, and little plugs of gauze steeped in it may conveniently be inserted in the openings in the carbuncle. Care must be taken that it is not kept applied to the uninvolved skin surface.

---

[17] THE LANCET, 1910, i., p. 1786.

Internal Remedies.

The internal remedies recommended are too numerous to mention. Brewer's yeast is a time-honoured one, but I have not found it any use at all. Preparations of nuclein appeared to do good temporarily. Sulphuric acid and the sulphides failed to do me any good. Sulphur is much more effectively taken as flowers of sulphur; about a drachm a day is a very useful remedy; its elimination by the skin is manifest, as silver coins in one's pocket get to look like gun-metal. Tonics of all sort are recommended, and are no doubt good in this as other asthenic states, but they are not curative. The collosol iron malt preparation is very good. Stannoxyl, a French preparation of stannium salts, I have found very useful in acne and boils, but it has not any marked effect on recurring carbuncles. Collosol manganese intramuscular injections, first recommended by my colleague Mr. J. E. McDonagh, have a very marked effect on staphylococcal infections. Carbuncles under this treatment sometimes dry up, shrink, and scab over in a remarkable manner, and of all the various methods of treatment I have tried in my personal experience of five years of carbuncles this alone has been effective. Collosol silver is also very useful as a local application. Opium, according to J. M. McLeod, is "better avoided." Paget says "its use is very valuable." I see no reason why opium should be abstained from in cases of carbuncle, if there are indications to give it; sleeplessness and pain sometimes demand it; it is the best treatment for the phagedæna and sloughy ulcers of legs, &c., and I have thought that carbuncles improved with internal administration of opium. Carbuncle in diabetes, and diabetes itself, are best healed by opium.

Vaccine Treatment.

I do not think severe acute staphylococcal infection is destroyed by vaccines, though its milder forms may be. At the 3rd London Hospital I saw many cases that had been treated by vaccines, but carbuncles persisted, and I think it is the opinion of those who saw very large numbers of cases in France that vaccines were ineffective.

Diet.

Some recommend port wine and other forms of alcohol, and others regard them as harmful. The administration of alcohol in carbuncle, as in other diseases, must be left to the common sense of the medical attendant. Dr. S. J. Nelson[18] lays great stress on dieting in patients with carbuncles, especially restricting sugars, raw fruits, coffee, and alcohol; milk or cream must be taken not with food, but an hour before; he utters a warning against the patient "over-eating, as is generally the case." But I think it is well to let the patient eat as he usually does; a patient who has carbuncles is not usually addicted to over-eating.

Operative Treatment.

Most modern surgical books recommend operation as the only treatment for all carbuncles. This is surprising, for most carbuncles will heal up without operation. I think the guiding rule should be to avoid operations unless there are special indications demanding it, but I am convinced that in some cases operation is necessary. Four, perhaps five, different procedures are described: complete excision; early incision; late incision; incisions with subsequent removal of slough and application of pure carbolic acid or other caustic; and there may be added subcutaneous incision.

(1) *Complete excision.*—G. Lenthal Cheatle[19] writes: "Incision is not enough to evacuate the contents; hence complete and wide excision is the best treatment." J. M. McLeod[20] writes: "Far the most satisfactory method of treating carbuncles locally is eradication of them by excision or scraping." J. P. Warbasse[21] says: "Extensive carbuncle of the neck with a boardy infiltration and dusky congestion is best treated by excision of the whole diseased area as though it were a tumour." J. H. Sequeira[22] writes, "Complete excision gives excellent results." Cheyne and Burghard[23] say: "The best treatment for a carbuncle of moderate size is to make an incision completely encircling it and to dissect it out cleanly under general anæsthesia; nothing is lost by excision, because the skin over a carbuncle is of little use in subsequent healing. The incision must be well beyond the limits of the disease, or local recrudescence is almost certain."

Schamberg[24] writes that "where septicæmic symptoms become marked it is justifiable to excise the whole affected area." Paget does not allude to total excision as a method of treatment in his careful clinical lecture on carbuncle, nor do Erichsen and many other authorities, and E. Doyen in a clinical lecture vigorously inveighs against it as replete with danger and almost sure to be followed by a succession of other carbuncles. The operation, a very severe one, greatly enlarges the area of the lesion; it tends to free hæmorrhage, which, in debilitated patients, is undesirable; it is practically impossible, however widely the "encircling" is made, to excise all tissue infiltrated with the causative organism; a huge raw crater is left, which soon discharges pus profusely, and pus full of virulent staphylococci. In consequence it is impossible to keep the skin dry; the pus is very irritating to the surface, giving rise to crops of satellite carbuncles; the cavity is intensely painful, and takes a very long time to heal. The operation produces much debility and disables the patient for months; in my experience, as in that of Doyen, it does not prevent but rather favours succeeding carbuncles. In addition, administration of anæsthetics to diabetic subjects with carbuncle is a danger, and the operation leaves a large cicatrix, which in some situations may be an undesirable result. The remark in Cheyne and Burghard's article that "the destruction of skin by the operation is of little consequence, because the skin over a carbuncle is of little use in subsequent healing" is not, I think, in accordance with the general experience, which is that the dusky inflamed tense skin over a carbuncle recovers to a surprising extent as the inflammation resolves, and that a very large brawny carbuncle, if not excised, leaves a very small cicatrix. It is noticeable that many of those who recommend total extirpation make the remark that subsequent skin-grating may be required. I think complete excision can be desirable only in very exceptional carbuncles.

(2) *Early incision.*—This procedure is recommended by Foote,[25] professor of surgery, New York Polyclinic Medical School: "It is important incision should be made through the skin before the process has extended widely." Warbasse[26] writes: "The surgeon should not wait until pus has collected, but free incision should be made at the earliest possible time."

I take "early" to mean that the skin is still unbroken. Paget, in a clinical lecture, writes: "Carbuncle in its first stage, when it is hard and still spreading, is generally intensely painful, and may be relieved of some of its pain by cutting, but healing without cutting is quicker than with; this also applies to subcutaneous incisions." I think the best advice is that of Erichsen, who writes: "Some surgeons uniformly adopt incisions, others with equal constancy reject them; I think the most successful treatment consists in allowing the question of early incision to be determined by the amount of tension in or around a carbuncle; should the parts be soft and relaxed an incision is not necessary, but on the other hand, if the tension be considerable, the pain great, and the constitutional disturbance severe, nothing gives such relief as a free and early incision." At the same time this negatives any very early incision, since the advice is to wait until carbuncles demand it. I think that if the incision be early and made to relieve tension, it is undesirable as a routine practice to excavate all the slough, which will certainly still be firmly fixed to living tissue, and I agree with W. Spencer and G. E. Gask,[27] who write, "A deep crucial incision was *formerly* a favourite practice, but it is much better to make an incision only through the skin down to the sloughing tissue."

[26] Surgical Treatment, vol. i., p. 253

A crucial incision is that usually recommended, although Erichsen observes that "a single straight incision does just as well." For mere relief of tension a single incision is often enough, but if the carbuncle tissue is to be scraped out, probably a second incision will be required.

(3) *Incision with application of caustics or corrosives.*—A very generally practised method is to incise, remove all slough, and rub in pure carbolic acid. If incision is made early to relieve pain and tension before the slough is at all loose, in my opinion it is better to abstain from the use of carbolic acid; but if the cutting is performed later and the slough separating carbolic acid should be applied. It perhaps lessens the probability of fresh carbuncles, though it certainly often fails to do so; I do not think it accelerates healing. The skin around should be oiled before the operation to protect it from any acid that may run over it, and the wound should not be packed with cotton-wool or other dressing steeped in carbolic acid, which cakes up with effused blood and prolongs unnecessarily the action of the acid. Whether simple incisions or incisions with use of carbolic acid be practised, they should not extend beyond the inflamed tissue on to the unaffected skin; it is quite unnecessary to open up new ground and to produce fresh edges of wound; the latter are intensely painful, especially if carbolic acid is used, and are almost certain to become infected. The inflamed skin of a carbuncle soon recovers as the carbuncle subsides, and there is no reason with a carbuncle the diameter of a halfpenny to make incisions of the diameter of a penny extending into unaffected skin.

Summary.

Summarising what I have said as to operation, I think operation is advisable in the following circumstances:—

1. Where the sloughing process is very deep-seated, perhaps under the fascia, and the inflammatory effusion is much obstructed in extending towards the surface; in these cases suppuration may extend widely and laterally, running between tracts of fascia and in the direction of least resistance. Pain is very intense, pyrexia may be marked, and serious constitutional symptoms arise. In such cases incision is imperative to give exit to the imprisoned pus.

2. Certain carbuncles, though not large, may be deep-seated and the slough may be very tough and thick; the process is subacute, the surrounding inflammation is not intense, and the amount of pus may be small. The opening formed in the skin may be single and very small at first, enlarging only very gradually; this and the toughness of the slough and its depth often imprison the small amount of pus there is beneath the slough. Eventually the opening in the skin becomes ulcerated away sufficiently for the slough to be got rid of, but it is a long process; toxins are absorbed, and in these cases I think incision should be performed.

3. Incisions to enlarge spontaneously formed openings in the skin or throwing them together are often useful as assisting discharge of slough and in accelerating healing.

4. Operation is sometimes required when final healing is prevented by tough bundles or bands of fibrous tissue which have resisted the sloughing process.

5. If either the first two conditions have led to opening a carbuncle by operation it is well to apply pure carbolic acid at the same time, but it is not desirable to incise a carbuncle otherwise progressing favourably in order to use carbolic acid.

TABES: ITS EARLY RECOGNITION AND TREATMENT.[1]

BY E. FARQUHAR BUZZARD, M.D. OXON., F.R.C.P. LOND.,

PHYSICIAN TO ST. THOMAS'S HOSPITAL, ETC.

Two Cases of Tabes.

IN October, 1912, I was consulted by a man who told me that he was 24 years of age and that he had suffered severe pains in his legs and slight pains in his arms for four years. He had seen various doctors, who had diagnosed neuritis, but had not been able to relieve him of his suffering. Further questioning elicited no other complaint in respect to his health except that he was lacking in energy and was easily tired on going upstairs. His description of pains led me to believe that he was suffering from tabes dorsalis, although he denied venereal infection.

Examination revealed no signs of any organic disease, with the single exception that his appreciation of pain below the knees, on the ulnar aspect of the forearms, and on part of the thorax did not appear to be quite up to the standard of other parts. The eyes were normal in every respect and the reflexes those of a perfectly healthy man. He could toe-and-heel a line backwards and forwards without hesitation, and the closure of his eyes had no ill-effects on his equilibrium. On the completion of my examination I told him that he was suffering from syphilis of the nervous system, and then elicited a history of irregular sexual intercourse on one occasion seven years before. This had been followed by a "pimple," for which he was treated by medicine for a short period. At my request his blood was examined by Dr. Carmalt Jones, who found a positive Wassermann reaction.

Eight years have elapsed since the date of this examination and diagnosis, during which period the patient has been having antisyphilitic treatment at more or less regular intervals. Without going into great detail, I may say that he has had 18 intravenous injections of salvarsan, kharsivan, or novarsenobenzol, two intramuscular injections of salvarsan, 460 mercurial inunctions, and a few courses of grey powder by the mouth. In other words, he has averaged 2½ injections of salvarsan and between 50 and 60 mercurial inunctions per annum. The treatment has not been regulated by Wassermann tests, but the latter have been made on ten occasions, including the one already mentioned. The blood Wassermann reaction first became negative in January, 1914, 15 months after the commencement of treatment. It became slightly positive in May, 1915, and again in September, 1917. On all other occasions the test proved negative. The cerebrospinal fluid was examined in May, 1914, when it gave a negative Wassermann reaction and yielded a count of 23 lymphocytes per c.mm. In January, 1916, the reaction was again negative and the lymphocytes numbered 8 per c.mm.

During these eight years the patient has been engaged in a strenuous business life with a very moderate allowance of holiday. He married in 1915 and is now the father of two healthy children. He plays a scratch game of golf and a game of tennis, with which he is quite content. In 1918 he was examined by a recruiting board and passed A 1, the verdict being upset by an appeal board at my request. To-day the patient presents no physical signs of organic disease, although a careful examiner may still detect some of the analgesia which I observed at my first interview. He has never entirely lost his pains, but the latter have not interfered with his active life, and he has frequently enjoyed several months together of complete freedom. An occasional bout of pain is easily dispelled by a dose or two of aspirin or phenacetin. Recurrences are usually associated with undue fatigue or with some more or less serious anxiety.

---

[1] A paper read before a meeting of the Section of Neurology of the Royal Society of Medicine on Dec. 9th, 1920.

This story raises some questions of interest, but before dealing with them I propose to recite another which may add value to the discussion.

In March, 1914, a man 38 years of age consulted me on account of severe pains in his arms and legs, from which he had suffered for six months. In other respects he was perfectly well, and he denied venereal infection. About five years previously he had been troubled with two or three sore-throats, for which he had had his tonsils enucleated. On examination he presented no signs of organic disease, and I could not satisfy myself that his sensibility was in any way abnormal. The pains were those of tabes dorsalis, and an examination of the blood revealed a positive Wassermann reaction. In April, 1914, I gave the patient three intravenous injections of salvarsan, and from that time until October he took courses of grey powder by the mouth. The pains disappeared after the injections and the blood Wassermann reaction was negative in October. I advised him to continue with occasional courses of mercury, and I have recently ascertained that he has remained free from pain and in perfect health.

Tabetic Pains.

In order to justify a diagnosis of tabes in the absence of physical signs it is necessary to state one or two facts about which there can be little disagreement. In the first place, the disease is one which attacks the afferent paths of the nervous system, and it is only reasonable to suppose that its earlier manifestations are of a subjective character—in other words, that complaints indicating a disorder of function precede those which are clearly due to structural defects. In the second place, it will be agreed that in a large proportion of cases of unmistakable tabes careful inquiry will elicit a history, often going back five, ten, or more years, of pains which have been regarded as neuritic or rheumatic in origin, and have not been associated with any other disability. Not once but a score of times have I asked a tabetic patient whether he has suffered from pains. After repeated denials I have altered the wording of my question and inquired for rheumatism. "Oh, yes, I have suffered from rheumatism for years." "What do you mean by rheumatism?" "Why, sharp, shooting pains in my limbs." This conversation shows how little the patient has associated his pain with the disability for which he is seeking advice, and incidentally how few patients understand the language they speak.

Granted that pains can be, and often are, the earliest signs of tabes, can they be distinguished from pains of other origin? I would answer this question in the affirmative and even go so far as to say that the pains of tabes described by a patient who is able to translate his feelings into intelligible language are quite pathognomonic. The fact that they are called lightning pains and that patients often say that they shoot up and down their legs has been responsible for a very general misunderstanding of their true character. When the patient states that they shoot up and down the limb he does not mean that each pain shoots from the hip to the foot or vice versa. He means that during an attack he may have pains first in the thigh and a few minutes later in the foot. If he is asked to describe them in greater detail he will inform you by gesture and by word that these pains have an axis, so to speak, at right angles to the surface of the limb. They stab like a knife or a darning-needle going in, or they resemble the effect produced by taking up the flesh, pulling at it, and letting it go. Further, the pains come not singly, but if not in battalions at any rate in platoons. They are rapidly repeated, several occurring in the course of a second or two, followed by a lull of longer or shorter duration. Bouts of paroxysms may last for a few hours to a few days and then cease for a time. Favourite sites for these pains are the heel, the inner aspect of the shin, and the inner aspect of the knee. The area within which they repeat themselves is small, described by the patient as the size of a crown-piece or no bigger than the palm of the hand. Between the frequent paroxysms these areas are often tender to light touch, so that the does not even like the contact of his clothes. atients are quite certain that pains may be provoked by a cold draught, by a change of weather, or even by a glass or two of beer. Others are equally sure that responsibility lies with fatigue or anxiety. In the early stages of the disease pains rarely occur during active exercise, but later on walking may be brought to a full stop by a sudden and overpowering paroxysm.

Before leaving the subject of pains let me make it quite clear that those I have described are not the only ones suffered by tabetic patients. There are deep, gnawing, aching pains in the bones, and others which have not the same diagnostic value. Let me also emphasise the fact that tabetic lightning pains must be recognised by their characters and not by their severity. Many patients confess to what they call "niggling pains," trivial in respect to suffering, but identical in nature with the lightning type.

It would be surprising if there were not other subjective phenomena in early tabes, and attention may be drawn to the not uncommon complaint that hot or cold water has become disagreeable or unbearable, that the patient is obliged to have his bath at a temperature which is described as tepid. Not that the hot or cold water provokes pains, but that it gives rise to a sense of great discomfort. This often applies to the whole surface of the body, although pains may be absent or confined to the lower limbs. Similarly it is not uncommon to hear that the fingers are numb when it is quite impossible to determine any disorder of sensibility by tests. This, of course, is not pathognomonic of tabes.

Treatment.

The necessity for advising antisyphilitic treatment of tabetic patients is not now so urgent as it was a few years ago, but it may be doubted whether the principles of this treatment are yet adequately recognised. We are all asked "How long must I go on with treatment before I am cured?" For many years my answer has invariably been, "For the rest of your life." I am never consulted about a primary chancre, but if I were my advice would be the same. It cannot be denied that we are not and never have been in a position to tell a patient that he has been cured of syphilis, and, as neurologists, we are now constantly seeing tabetic patients who have been cured of syphilis by the arsenical compounds, just as 15 years ago we saw those who had been cured by mercury. I maintain that the only honest advice we, as medical men, can give to patients suffering from any syphilitic disease is to the effect that they should continue to have periodic courses of treatment for the rest of their lives. Tell them that prevention is better than cure, and that they must regard this precaution as a method of insurance. In my experience so many victims of tabes and other syphilitic nervous diseases have allowed valuable time to slip by owing to negative Wassermann reactions that my confidence in this test as a method of regulating treatment is shattered.

Conclusion.

Is there any lesson to be learned from the story of the two patients which I have presented to you? The first man was infected with syphilis 15 years ago, and has undoubtedly suffered from tabes for 12 years, during eight of which he has been under treatment. To-day he would be passed as a first-class life by any medical officer of an insurance office who did not know his history. It would be unwise and unjustifiable to say that he is cured, but it is difficult to believe that the natural progress of his disease has not been arrested. And it must be remembered that he wasted four years before his symptoms were recognised and treated. The second patient was more fortunate. Only six months were wasted, and the result of treatment was rapid and lasting, judged by the fact that he has now enjoyed six years of freedom from any kind of symptom. These are not the only cases of the kind which have come under my observation, but I regret to say that it is a rare experience to be asked to see a patient suffering from tabes whose symptoms have not been long-standing.

It is obvious that the value of these observations depends on the reliance which can be placed on the description of pains given by patients, and on the criterion the description affords for purposes of diagnosis. In many cases the description is vivid and easily recognised. In others it can only be elicited by patient cross-examination, avoiding the employment of leading questions. After many years of critical study of this problem I am convinced that the lightning pains of tabes are, for practical purposes, pathognomonic, and that they can and should be recognised before they are many months old. Treatment initiated before physical signs are apparent is not only possible in many cases, but is likely to be attended by good results if persevered with to the end of the chapter.

DIFFICULT CASES OF
INFANT FEEDING AND MANAGEMENT.[1]

BY RALPH VINCENT, M.D.DURH., M.R.C.P.LOND.,
SENIOR PHYSICIAN AND DIRECTOR OF THE RESEARCH LABORATORY, THE INFANTS HOSPITAL.

I BEGIN by impressing upon you the importance of exact diagnosis. Start right with an accurate diagnosis of your case, and you are on the way to right treatment and correct management. Much confusion exists in the use of such terms as "wasting disease," "atrophy," &c.; and in reference to the wasting infant it is necessary for us to be quite clear on the following points: (1) Is the failure to thrive associated with the condition of the infant at birth, or has it arisen since birth? (2) If the condition was present at birth, is it a case of imperfect development—i.e., immaturity—or is it due to specific disease?

If the wasting baby was healthy at birth, then the case is one of malnutrition. Do not speak of "atrophy," meaning loss of function, in the case of a baby who has never had the function to lose. Recollect how easy it is to slip from a rather casual way of looking at the case into thoroughly wrong diagnosis and treatment. The infant is a wasting infant, is it not? Wasting implies malnutrition, and the treatment of malnutrition is correct feeding. But, unfortunately, the best feeding in the world will not do much for this particular wasting baby. The infant is *not* suffering primarily from malnutrition; it is suffering from congenital syphilis and will not thrive unless mercury is given systematically. Bear with me if I seem to labour this point of diagnosis, for it is no uncommon experience for me to find cases of congenital syphilis treated with patent foods and cases of malnutrition treated with mercury.

Congenital Syphilis.

Congenital syphilis is very varied in its manifestations. It is seen in three stages: (1) where the fœtus dies in utero; (2) where the infant is born with the disease quite evident; and (3) where the infant at birth appears to be quite healthy. Only the third stage concerns us to-day, and here it is very easy to go wrong unless the doctor is alive to the possibilities. The cases that give rise to doubt and difficulty are cases of remote infection. At birth the infant is quite healthy and vigorous, and its weight good. The specific symptoms gradually begin to appear. The first signs are not those generally recognised as syphilitic, for these are not seen till later. The infant's crying is often characteristic, being almost continuous; there is a wildness, a frenzy, about it that takes it out of the category of the ordinary infantile plaints. Restlessness and sleeplessness are prominent features. A little later snuffles may appear, but if alone the latter is useless for diagnosis; many young babies, especially those with malnutrition, show this sign. Ulceration of the palate often occurs, and the ulcers are generally symmetrically disposed on both sides of the middle line. The "café-au-lait" complexion so much dwelt on by various writers is not, in my opinion, of much value for diagnosis; in many cases of well-marked congenital syphilis there is no sign of it, nor is it in the least pathognomonic. The most marked instances of this complexion occur in infants suffering from chronic intestinal catarrh.

In cases of congenital syphilis it is of the utmost importance that the earliest possible diagnosis should be made. I have referred, for instance, to ulceration of the palate. With early diagnosis and appropriate treatment all such lesions should be prevented. Pay no attention to the history of the case. If you are interested in amateur fiction you may find the "history" of interest. Make your diagnosis on the signs and symptoms.

Some years ago I was asked by a colleague to see a young baby. I diagnosed congenital syphilis. He could not accept this diagnosis as it went clean against all his knowledge of the case. He had attended the mother in her first confinement. He had seen the first baby from birth, and never had there been a sign of syphilis. Moreover, my own diagnosis—remote infection—put the other possible explanation—recent infection—out of count. However, I stuck to my diagnosis and advised my colleague to wait for a favourable opportunity and talk the matter over with the father. He did, and he elicited the history that as a young man the father had contracted syphilis, that he was thoroughly treated and had been pronounced cured, but in order to be on the safe side he had received a mild course of anti-syphilitic treatment some months before and for about a month after his marriage.

This case is, I think, worth quoting, because if it had not been for the diagnosis the true history of the case would never have been elicited.

On pp. 281–2 of my "Nutrition of the Infant" (fourth edition) you will find the diet chart and the weight chart of D. F. (R. 1083). That case shows you very clearly the difference that diagnosis makes. The correct diagnosis was not made between June 10th and August 28th, and the infant was in a critical condition. On August 28th the proper diagnosis was made. Mercury was administered, and from that time the weight chart was as satisfactory as it had previously been unsatisfactory. Do not, however, go away with the impression that I am persuading you to give hyd. c. cret. to babies on the off-chance that they may be syphilitic. That is very far from my intention. Mercury for syphilis and not for malnutrition is what I want to say to you.

Treatment of Immaturity.

Now we may pass from congenital disease to congenital imperfection. Immaturity may be, and usually is, due to prematurity, but not all immature infants are premature. As a matter of fact, a full-term immature infant usually presents greater difficulty than a moderate case of prematurity. Some 15 years ago I endeavoured to arrive at some prognostic criterion of viability by means of the weight of the infant. In the atrophic infant I found as a rule that the prognosis was bad if the infant weighed less than one-half of the normal weight for its age. But in infants at birth, or very shortly after birth, I found the weight almost useless as a basis for prognosis; in this case the length of the infant was the most potent factor. The normal infant at birth is 21 inches long, and this measurement is extraordinarily constant. The case of an infant under 20 inches in length is difficult, and that of an infant under 19 inches almost hopeless. In the condition of immaturity the strain generally falls upon the digestive system. Either the infant has to be fed upon an extremely delicate food, because anything approaching the normal standard of milk mixture for a young infant causes digestive disturbance; or, if a moderately good food is taken without indigestion, the infant nevertheless fails to gain in weight.

I may quote from the case of an infant sent to me by Dr. T. Luson, of Kingston-on-Thames, many years ago. After the infant had been two months under my care I wrote to Dr. Luson:—

> "It is a remarkable illustration of this class of case. The infant is taking a large amount of highly nutritious food, there is no digestive disturbance of any kind, and yet she makes absolutely no gain in weight. She has not yet reached the stage of structural creation."

---

[1] Being a Post-Graduate Lecture delivered at the Infants Hospital, London, on Nov. 16th, 1920.

Shortly after this was written the infant started to increase its weight, and steadily rose from 6 lb. 14 oz. to 8 lb. 14 oz. in the course of seven weeks.

In the treatment of premature infants the two considerations of greatest importance are (1) warmth, (2) delicate adjustment of diet. In my experience the best method of maintaining a normal temperature in the infant is to use an electric radiator. The room should be adequately warmed by a coal fire, the window being kept slightly open as a rule to ensure an adequate supply of fresh air. The infant's cot should be placed in a corner of the room surrounded by screens and with the electric radiator underneath or near to it. By altering the position of the radiator and by adjusting the current it is comparatively easy to maintain the temperature near the cot fairly constant. For a premature infant I generally recommend that the temperature should be not less than 80° F. On no account use an "incubator." Almost any method is preferable to shutting a baby up in a box of that kind. See that the extremities are covered with cotton-wool. If the feet are warm I consider the temperature conditions satisfactory.

Many premature infants do fairly well for a week or two and then die, not infrequently because they have been fed on foods enabling them to "carry on" for a short period, but entirely failing to provide them with the stimulus necessary to promote growth and development of function. Fresh milk modified to suit the delicate condition of the infant is essential.

Post-natal Breakdown in Healthy Infants.

From this necessarily brief summary of the difficult cases in infants as a result of ante-natal conditions I pass to the consideration of the baby who is thoroughly healthy at birth and "goes wrong" a few weeks or months after birth. In my previous lecture[2] I dealt with the general principles underlying the feeding and management of the normal infant, and I propose now to deal as succinctly as possible with the treatment of nutritional disorders and disease. Here is a typical history:—

> The infant did well for about a month, and then vomiting occurs, motions were rather undigested, and weight no longer increased. The baby was breast-fed; the monthly nurse gave the mother port wine with increased food; the baby got worse, although the doctor was called in and did what he could. A specialist was called in and ordered a remarkable concoction of drugs, bread, and milk. The same specialist was again called in a few days later, and this time ordered asses' milk. A few more days elapsed, and a most distinguished physician was called in. He made a sensible attempt to stem the tide of the disaster, ordering a wet nurse without delay. She arrived, and in the following 24 or 36 hours a material improvement was evident, which unfortunately was not maintained; in the succeeding 24 hours the baby had violent diarrhœa and was seriously collapsed. Still another specialist was sent for—this time myself. I ordered a dose of castor oil and a little brandy, two "feeds" of saline lactose to be followed by a milk mixture of the composition: fat, 1·25 per cent.; lactose, 4·00 per cent.; whey proteins, 0·50 per cent.; caseinogen, 0·25 per cent.; lime water, 5·00 per cent. The infant made an uninterrupted recovery.

I want to draw your attention to certain cardinal points. There could not have been very much wrong with the baby when the simple measures I adopted were all that was required to effect a rapid and complete cure. Let me summarise as follows the mistakes made in this case: (1) overfeeding of the mother; (2) still worse, when the baby was beginning to show signs of indigestion, the monthly nurse increased the mother's diet; and (3) as the infant had to be removed from the breast by reason of its severe indigestion, the indication was for a specially diluted milk for a few days; instead of which a mixture of equal parts of milk and water with added cream was given. A big, vigorous, healthy baby might be able to tackle such a mixture, but to order it for a six-weeks' old infant that for a fortnight past had been suffering from gastric and intestinal disorder was very unwise. I pass over the efforts of the first specialist because they were, in my opinion, merely silly; the second was a first-rate physician, and his advice might have been successful, but even he would not leave the baby alone. Why be so keen on feeding a baby whose stomach is thoroughly upset? True, the wet nurse's milk suited the baby admirably for rather more than 24 hours. How was it that diarrhœa with collapse occurred the day after? The explanation was not difficult; the wet nurse came from Queen Charlotte's, and was a poor woman who went for her meals to the kitchen of a well-appointed house, and the generous diet sent the fat in her milk up with a bound, with disastrous results for the baby.

And what am I to say about the milk mixture that did meet the requirements? The fat was only about one-third of the normal amount, a fair amount of lactose was given, for it is readily assimilated, and of whey proteins, for they are very light and place little strain on the digestive organs. The curd-forming element was, of course, reduced to a very small amount. But this is not all—the "milk" mixture that saved the baby contained no less than 94 per cent. of water. There is one other moral attaching to this case. Those I discussed at the outset were cases of inherent difficulty, for no doctor who knows his work will say that an infant only 19½ inches long at birth is not a difficult case. But here no such explanation is tenable. The difficulty was, to put it as tactfully as possible, due to conditions not present at the time of birth.

Nervous Exhaustion.

The next class of difficult case I have to discuss is one to which I would invite your close attention, for there is, according to my experience, no class of difficult case so little understood by doctors in general or, at any rate, so imperfectly appreciated. I have seen these cases everywhere, and it almost invariably happens that the doctor in charge of the case is distinctly sceptical when he hears my diagnosis. His general attitude is that he hopes it may be true, but fears it is too good to be true—the diagnosis is too optimistic. The very last case I saw before I joined the army was at a consultation in Essex, and the doctor said to me, "This is a very rare case, is it not?" I could not help smiling, for his was the third case I had seen that week. When I see these cases the first thing I do, as soon as possible, is to order opium for the baby—one-quarter of a minim of nepenthe—to be repeated in one hour if required. Now let me attempt to give you an outline of the case.

> The parents are healthy, highly-strung people. As a rule, they are not in the least "neurotic," but they are on the nervous side. If I say that the mother is a charming woman, a thoroughly good sportswoman, and generally "one of the best," you will the better appreciate the type of parent I mean. The history of the case, allowing for the necessary human differentiation, is fairly constant. The mother's milk, as a rule, is scanty and soon fails. Some milk mixture is tried and the baby is much disturbed by indigestion, generally accompanied by a good deal of pain. Pain, indeed, is one of the first symptoms. Various foods and various remedies are tried, but nothing avails, and the first stage of the case ends in really terrible trouble. The baby has had nothing in the way of restful sleep for something like 48 hours, and everybody is distracted by its violent screaming and obvious suffering. Intermingled with this first stage or following closely upon it are a whole boat-load of symptoms. Vomiting may be intense so that even plain water will be promptly expelled. Intense spasm of the colon may be present, spasmodic movements of the head and limbs are fairly common, and epileptic seizures may be seen.

But, indeed, the symptoms are protean. Do not worry about particular symptoms so long as you can get the size of the case. The diagnosis is nervous exhaustion, with, as a rule, intense neuro-muscular irritability. When I had cured one of these babies one of the most charming mothers in this country said to me, "I have never before heard of a rest-cure for a three months' old baby." That remark gives you a valuable clue to the whole line of treatment, which is as follows:—

> (1) Remove the baby from the extremely well-lit nursery with its very sanitary oil-cloth floor, and place it in a semi-darkened, well-carpeted room.

---

[2] [illegible] al Points in Infant Feeding, Clinical Journal, [illegible] 3, 1920.

(2) See that the nurse is quiet and gentle; everything she does to the baby must be done gently.

(3) The baby must be away from all noise on the stairs or outside the house. In one case I noticed distinctly that every time the dog in the stable-yard barked the baby squirmed. Remove that dog.

The food as a rule should be a nourishing one. Too much dilution will not be useful, for the nervous system requires fat, and, generally speaking, the baby needs building up. Here is the sort of milk mixture that I have in mind for a three months' old baby suffering from neurasthenia: fat, 3·00 per cent.; lactose, 7·00 per cent.; whey proteins, 0·75 per cent.; caseinogen, 0·75 per cent.; lime water, 5·00 per cent.

In regard to milk mixtures I always think in terms of the relative proportions of the constituents, and I would wish you so to think, for I know of no other way by which you can keep constantly in your mind the related factors of the requirements of the infant and the constitution of the milk mixture. But I recognise that my lecture would not be sufficiently practical or useful to you if I confined myself strictly to writing the prescription. I must try to tell you how to get the prescription dispensed, and so must interpose a summary description of my "fat whey" method worked out in the research laboratory of this hospital some years ago, and since then extensively employed in our out-patient department and elsewhere:—

Add rennet to one quart of milk; raise the milk to 100° F.; stir the milk all the time the curd is forming; as the curd forms gradually press it down to the bottom of the jug with a large spoon, so that the curd is finally pressed into a hard lump at the bottom of the jug. Remove the lump of curd, raise the fat whey to 150°, cool rapidly, and then add the required proportion of milk.

Note that the fat whey should only be *raised* to (*not kept at*) 150°. This procedure is necessary in order to kill the rennin ferment. If this were not done the rennin in the fat whey would curdle the added milk when the mixture was warmed to 100° before it was given to the infant. By means of fat whey, water (if necessary), and milk all sorts of combinations may be obtained. For example, three parts of fat whey to one of milk makes a mixture very closely approximating to the prescription I have just given. This mixture is, however, as compared with the prescription, a little deficient in sugar, but there is, of course, a very easy correction for that deficiency, and you need not particularly worry about the added sugar being milk-sugar. There is plenty of lactose in the mixture.

Intestinal Disorders.

I pass now to a brief consideration of intestinal disorder. The cases I propose to discuss are full of difficulty and anxiety. The baby is suffering from diarrhœa, is cold, very ill, and a fatal issue is probable unless you put a stop to the threatening conditions. But do not concentrate your attention too much on the diarrhœa. Long ago Dr. Emmott Holt, of New York, in his admirable book, "Diseases of Infancy and Childhood," referred to the cases in which constipation occurs, remarking that in acute intestinal intoxication diarrhœa is a conservative process of the greatest possible value, and I cordially agree with him. In 1887 Ballard, reporting upon his investigations into the disease known as "epidemic diarrhœa," stated that in his opinion the disease could run its course from first to last, and even to death, without any diarrhœa at all. In my paper on the Bacteriological Diagnosis and Treatment of Alimentary Disease in Infancy and Childhood[3] you will find a fairly complete account of the subject; I can now only give you a very brief summary.

The first thing is to give the infant a good dose of castor oil. Stop all food and give warm sweetened weak tea—one of the best sustaining tonics for the infant and, generally speaking, much better than brandy. If the collapse is urgent, administer by inhalation 1 minim of amyl nitrite—the most potent restorative in all cases of infantile collapse and extremely effective in cases of convulsions. I have long abandoned the subcutaneous and intravenous injection of normal saline solution. If the baby cannot swallow, administer amyl nitrite and then give the normal saline by the mouth in a bottle. I have never known a baby to refuse it, and administered in this way it is extremely effective and gets into the baby much more quickly than by any other method. All fluids administered at this period should be at "super temperature," 110°. A direct microscopical examination of the intestinal dejection is of great importance, for, as a rule, this enables us to put the case into one of two groups: (1) Gram-positive organisms dominant—probably a case of lienteric diarrhœa; or (2) Gram-negative organisms dominant—a case of intestinal toxæmia.

The cases with Gram-negative organisms dominant are serious and, roughly, fall into two types of intestinal toxæmia: (1) acute, (2) chronic. The acute type is very serious.

The importance of the bacteriological diagnosis in these cases can scarcely be exaggerated, for as long as the Gram-negative organisms are dominant the infant is in danger. I should never feel justified in giving a favourable prognosis until I had satisfied myself that this toxic dominance had been obliterated. If the case is a toxic one, fresh milk is essential. Any form of cooked milk or food other than milk handicaps the growth of the lactic organisms and encourages the growth of the toxic organisms. In bad cases of toxæmia fresh milk will not be anything like powerful enough, and cultures of the *Streptococcus lacticus* should be administered with every feed.

In the case of lienteric diarrhœa the treatment is very different. The Gram-positive organisms are dominant. The dejections are acid—very likely much too acid. In such cases a small dose of opium is a very valuable remedy, as it soothes the irritated intestines. The infant should be kept very warm and should not be given fresh milk until the diarrhœa has ceased. In these cases I find that the Ideal brand of unsweetened condensed milk much diluted is, as a rule, a very good food to begin with. In the course of its preparation it would appear that saccharated lime is added to the milk; this combination appears to be very well suited to the needs of the infant suffering from lienteric diarrhœa.

In all cases of serious intestinal disorder the treatment must be conducted with great care. Sometimes the kind of food previously given is so ill-suited to the infant's needs that it must be stopped forthwith. But in other cases the changing of one kind of food to another and very different kind of food is too violent a procedure. For example, I am never satisfied until the infant is getting fresh milk in suitable quality and quantity, but this does not mean that I promptly order a milk mixture suitable for a normal infant. The worse fed a baby has been the less likely it is to digest milk. The milk mixture must be given much diluted, and at first it should not be given at every feed. The proper food must be gradually introduced, for a delicate infant cannot straightway digest fresh milk after it has been deprived of milk for a considerable period.

Conclusion.

Before bringing my lecture to a close I wish to refer as briefly as possible to broncho-pneumonia and the importance of correct feeding in these cases. The baby has been very ill with all the signs and symptoms of pneumonia, but the temperature has fallen; the breathing is much easier, and altogether it is clear that the severity of the attack has passed. Just at the time, however, that the rapid recovery of the infant is expected it becomes clear that something is wrong, and it is very often at this stage of the case that I am called into consultation. These are cases of colon toxæmia; the infant has been swallowing large quantities of mucus, and the decomposition of this mucus in the intestine is responsible for the condition. The leading symptoms are apathy, great drowsiness, weakness, and refusal of food. Always feed infants suffering from broncho-pneumonia on fresh milk and keep the bowels open, so that the mucus is speedily voided.

You will allow that it is not an easy matter to select the material for a single lecture from the experience of some 20 years' dealings with difficult cases in babies. My main idea throughout has been to deal with the kind of case that I have actually found, according to this experience, to be the cause of difficulty and trouble.

DIABETES INSIPIDUS COMPLICATED BY INTERMITTENT GLYCOSURIA.

BY GEOFFREY EVANS, M.B. CANTAB., M.R.C.P. LOND.,
PHYSICIAN TO OUT-PATIENTS, METROPOLITAN HOSPITAL; CHIEF ASSISTANT TO A MEDICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL;
AND
R. L. MACKENZIE WALLIS, M.A., M.D. CANTAB.,
CHEMICAL PATHOLOGIST TO ST. BARTHOLOMEW'S HOSPITAL; LECTURER IN CHEMICAL PATHOLOGY, ST. BARTHOLOMEW'S HOSPITAL MEDICAL SCHOOL.

THE earliest record of the occasional presence of traces of sugar in the urine of diabetes insipidus is a reference to two cases by Sir William Roberts[1] in 1876. Naunyn[2] in his monograph on diabetes mellitus refers to a single case in his own experience, but no details are given. Von Noorden[3] mentions the fact of transitory glycosuria in diabetes insipidus, though he does not discuss the condition nor describe a case. The only complete record of a case of intermittent glycosuria that we have found is one reported by Mackenzie Wallis and Roper.[4] The main feature of this case was the association of glycosuria with "acidosis" and creatinuria. The presence of polyuria was noted, but its bearing on the case was not discussed. In the light of the two cases here recorded it is probable that the case was of similar nature.

Clinical Record.

CASE 1.—A. Z., age 32, of Jewish nationality, a market porter, was admitted to St. Bartholomew's Hospital under the care of Dr. J. H. Drysdale, on 22/1/20, complaining of loss of energy and strength. The man ascribed his symptoms to the strain of army service, and stated that he had good health until the spring of 1918, when he first complained of a dull pain in the small of the back. He went sick in May, 1918, on account of this pain, and about this date he first complained of thirst, weakness and drowsiness. He described his weakness as a tired feeling, a "droopy feeling," as though he had no life in him. This feeling was liable to occasional aggravation, for which he used the word "drowsiness." At the same time he suffered from a "tight feeling" over both eyes (deep supra-orbital), which sometimes amounted to a headache. He was admitted with these symptoms to the Mile-End Military Hospital, where sugar was found in the urine, and the case was diagnosed as diabetes mellitus. He was told not to eat potatoes, and he was invalided from the army on his discharge from hospital in July, 1918. After his discharge from the army he returned to his work as a market porter, but after six weeks' work he was unable to continue on account of pain in the back and weakness. The symptoms as outlined above have persisted and varied little since their onset. There is no history of past illness, and V.D. is denied. It appears from his statements that he has had polyuria for the past ten years.

Family history.—Father and mother alive and well. Wife healthy, and has had no miscarriages; he has two children—one, aged 8, is delicate and has had pneumonia twice; the other, aged 4, has "always seemed to pass a lot of water," and in infancy suffered from enuresis. She is otherwise bright and active, and a single morning specimen of urine brought for examination was normal.

Condition on admission.—The salient facts observed on admission were noted from time to time unchanged from the date that he first came under observation in May, 1919. General appearance: small build, good physique, no skeletal deformity. Skin and hair natural. The upper lids drooped somewhat and the eyes were a little prominent: the sclerotics were always somewhat congested, so that the facies suggested a man who has been drinking the previous night. The tonsils were hypertrophied, there was marked pyorrhœa alveolaris. Eyes: pupils equal, normal reaction to light and accommodation; optic discs and visual fields normal. In the neuro-muscular system there were no abnormalities, except that neither the knee-jerks nor the ankle-jerks could be elicited; other reflexes were normal but weak. Cardiovascular system: normal. Blood pressure 113/68. Kidneys: the following figures give the fluid intake and output in ounces on successive days under observation in hospital—fluids/urine, 160/136, 192/146, 90/80, 172/–, 140/80, 140/145, 147/110, 110/92, 101/104, 84/60, 62/60, 85/96, 87/–. The following figures give the specific gravity of 24-hour specimen [illegible] 1008, 1010, 1010, 1010, 1015, 1012, while it was on two [illegible]s in single specimens 1020 and 1025. There was [illegible] of micturition, and the above figures show the amount of polyuria. During the six weeks that the patient was under the observation of Dr. W. Langdon Brown in 1919 sugar was only found in the urine in very small amounts on two occasions. In general the urine was clear, pale amber in colour, with a nebula deposit, never containing albumin or diacetic acid.

The blood Wassermann reaction was negative. The diastase in the urine was 22 units. X ray examination of the skull on 13/9/19 by Mr. Martin Berry showed a slightly expanded sella turcica, and the posterior clinoid processes appeared thinned; a faint shadow was visible in the region of the pituitary body. From the skiagram it did not appear that the condition was necessarily beyond the limits of normal variation. A later skiagram taken by Mr. H. George in February, 1920, was reported on as follows: "The pituitary fossa is a little on the large side, its shadow measuring 14 × 10 mm. (normal = 12 × 9 mm.), the posterior clinoid processes are somewhat thinned and the sella turcica somewhat enlarged."

Other points noted were as follows: the hands were small, the fingers markedly square-ended; the feet and toes were of normal shape, as were the ears and nose. Constipation was the rule; sleep was undisturbed and appetite good. Loewi's reaction was negative.

CASE 2.—P. M., age 35, war-pensioner and previously a gas-works stoker, was admitted to St. Bartholomew's Hospital under the care of Dr. Drysdale, 28/2/20, having been sent to Dr. Mackenzie Wallis by Dr. A. S. Woodwark for a blood-sugar analysis. His chief complaint was of headache and pains in the small of the back. On account of the clinical resemblance of the case to the foregoing patient, who was at that time in the hospital, he was admitted for examination. When in France, working in a Labour Corps behind the line, and shortly after rejoining his unit from sick leave in England, he complained of the onset at one time in October, 1918, of thirst, polyuria, and headache. The headache was a pain across the right eye just above the eyebrow. At about the same time he first complained of pain in the small of the back. He was kept under observation and was told that sugar had been found in his urine. He was ordered a restricted carbohydrate diet consisting of meat, dry toast and milk, without jam, sugar, or potatoes. Fourteen days later he was free from headache and thirst and felt much better; he accordingly rejoined his unit. Shortly afterwards he complained of pain in his stomach; this was diagnosed as dental dyspepsia. From this date on he passed from one hospital to another, only once returning to his unit for one week, being occupied, apparently without any particular symptoms of disease, until his demobilisation in November, 1919, in dental treatment. Nine days after his return home in November, 1919, he complained again of the onset of headache, thirst, and pain in the back. These symptoms persisted without variation until his admission to the hospital. He has had polyuria as long as he remembers, and has had difficulty in holding his water; he has to pass it once or twice during the night. Except for occasional quinzies no past illnesses. Venereal disease was denied. In May, 1915, he was rejected for the army on account of being round-shouldered and deformity of the feet (hammer toe). In July, 1918, having been recruited for a Labour Corps in the meantime, he was invalided home from France with inflammation of connective tissues, legs and feet. It was after rejoining his unit from his illness that his pituitary symptoms first developed.

Condition on admission.—General appearance: considerable growth of coarse dark hair in all the normal regions. It was a marked feature of his appearance, though not beyond the normal variation. The skull was dolichocephalic and the lower jaw prominent. There was marked dorsal kyphosis and some degree of lumbar lordosis; the kyphosis was attributed by the patient to carrying a heavy weight on the back soon after leaving school. No other skeletal deformity was present. He was a man of low intelligence, but in other respects cerebration was normal. In addition to the symptoms already noted he complained of a feeling of tiredness; he explained this symptom by standing at attention and saying that he could not stand thus, but only like this, and then he let his shoulders flop forward and stood with knees a little flexed. The tongue was clean and moist; the tonsils hypertrophied; all teeth except three were missing, and their place taken by false dentures. The cardiovascular system was normal. The heart gave evidence of slight hypertrophy, and there was slight thickening of the radial artery. These signs were not more than might be expected in a gasworks stoker 35 years old. The blood pressure was 110/65. The neuromuscular system was normal. The optic discs were normal. There was no refractive error; the visual fields were normal; all reflexes were brisk and natural. There was no evidence of kidney disease. The urine on boiling gave a faintest cloud; there was, however, no precipitate with salicyl-sulphonic acid, and this was decided to establish the fact that no albumin was present. Many specimens were examined for casts; occasional hyaline casts were found in centrifuged deposits both from fresh and 24-hour specimens, but no abnormal deposit was found. From this aspect the urine was therefore normal. During the period of the patient's observation in hospital a trace of sugar was found in the urine in four specimens. This sugar was identified as glucose. The following figures give the range of variation of fluid output and intake for 24-hour periods: Intake/Urine = -/64, -/34 plus, 84 plus/108, 81/72, 78/90, 81/84, 95/112, 72/120, 88/106, 102/106, 91/104, 82/112, 97/100, 91/93, 99/90; these figures do not correspond accurately, as the patient was in some respects difficult to control. The following figures give the range of variation in specific gravity of 24-hour specimens: 1013, 1005, 1010, 1010, 1011, 1007, 1010, 1010. The urine was pale, slightly hazy, though perfectly clear immediately it was passed. The faint haze on boiling not due to albumin led to a suspicion of cystitis, although there was no other evidence of this complaint. A catheter specimen of the urine was examined bacteriologically, but both aerobic and anaerobic cultures were negative. Diacetic acid was never found in the urine. As regards other tests, the blood Wassermann reaction was negative; the diastase in the urine was 22·2 units (normal). Loewi's reaction was positive on March 5th, though negative at a later date (15/3/20).

Without other treatment than rest in bed the patient suddenly recovered of his symptoms on March 6th. He said on the following day that he felt quite well, that he had lost his headache and pain in his back, and that his energy had returned. There were no outward signs of this change in his condition. The polyuria continued as before, and though he seemed to drink as much as previously he said that he had lost the thirst of which he had previously complained. While not attaching too great importance to signs whose significance is still an uncertain matter, it is noted that the Loewi's reaction was positive while he felt ill and negative when he felt that he had recovered. A difference in the response to sugar was also noted.

Chemical Pathology.

Technique.—Specimens of urine were repeatedly tested for sugar by chemical and polarimetric methods. A negative reaction with Benedict's solution was regarded as indicating the absence of sugar in pathological quantity. Blood sugar determinations were made by the writer's method,[5] and the diastatic activity of the urine by a modification of the original Wohlgemuth method.

CASE 1.—15/9/19. Blood sugar = 0·1 per cent. (normal). January-February, 1920, sugar tolerance tests:—28/1/20: 6 A.M., 50 g. glucose taken; no glycosuria followed. 30/1/20: 6 A.M., 100 g. glucose taken. Urine: 6–7 A.M., vol. 190 c.cm., 0·595 per cent. sugar, total 1·13 g.; 7–8 A.M., vol. 160 c.cm., 0·356 per cent. sugar, total 0·569 g.; 8–9 A.M., vol. 165 c.cm., 0·00 per cent. sugar, total —; 9–6 A.M., vol. 1770 c.cm., 0·356 per cent. sugar, total 6·3 g. Report: The patient passed 0·1 per cent. sugar in the urine before the test, and this amount was increased after taking 100 g. glucose. The tolerance appears, therefore, to be less than 100 g. and more than 50 g. 9/2/20: 6 A.M., 75 g. glucose taken. Urine: 6–7 A.M., vol. 200 c.cm., 0·2 g. per cent. sugar, total 0·4 g. Urine examined in hourly specimens afterwards contained no sugar. Report: These observations show that the sugar tolerance of this patient lies above 50 and below 100 g. 5/2/20: 10.50 A.M., blood sugar 0·09 per cent., urine no sugar; 11 A.M., 25 g. glucose taken; 11.15 A.M., blood sugar 0·122 per cent.; 11.30 A.M., blood sugar, 0·137 per cent.; 12 noon, blood sugar 0·09 per cent.: 12.30 P.M., blood sugar, 0·09 per cent. Urine, 11 A.M.–12 noon, contained 1 per cent. sugar. Total vol. 245 c.cm. Total sugar, 2·45 g. Report: Tolerance on this day was lowered. The blood sugar showed a practically normal change following 25 g. glucose, but the threshold value was lowered.

CASE 2.—2/3/20: Before test, blood sugar 0·11 per cent.; urine, no sugar. 11 A.M., 50 g. glucose taken by mouth. 11.15 A.M., blood sugar 0·207 per cent. 11.30 A.M., blood sugar 0·307 per cent. 12 noon, blood sugar 0·226 per cent. Urine, 11 A.M.–12 noon contained 0·7 per cent. sugar; total volume 310 c.cm.; total sugar 2·2 g. Report: The blood sugar showed a definite response to the ingestion of 50 g. glucose, the marked hyperglycæmia being maintained for over one hour. It is evident from the figures that the leak point for sugar is high but the tolerance low.

After the patient had made a clinical recovery another tolerance test was performed with the following result: 15/3/20: Before test, blood sugar 0·1 per cent.; urine, no sugar. 11 A.M., 50 g. glucose taken by mouth. 11.15 A.M., blood sugar 0·113 per cent. 11.30 A.M., blood sugar, 0·140 per cent. 12 noon, blood sugar, 0·122 per cent. 12.30 P.M., blood sugar, 0·110 per cent. 1 P.M., blood sugar 0·09 per cent. Urine, 11 A.M.–12 noon, contained no sugar; urine, 12 noon–1 P.M., contained no sugar. Report: The lowered glucose tolerance observed 13 days previously had disappeared, corresponding with the improvement in the condition of the patient. The response to the sugar ingestion was normal, and there was no glycosuria.

The nature of the reducing substance in the urine in both patients was established as being glucose by the fact of its being dextro-rotatory, and by the preparation of glucosazone crystals.

Discussion.

The most constant and important signs of disease shown by these two patients were polyuria and the secretion of urine of low specific gravity. Chemical examination of the urine, microscopical examination of its deposit, and clinical examination of the cardiovascular system ruled out renal disease as a cause of the abnormal condition of the urine. Nor can it be ascribed to polydipsia or to gross disease of any part of the nervous system, in so far as such disease can be excluded by clinical examination. It is considered that, in the absence of demonstrable functional or organic disease of the central nervous system and kidneys, the diagnosis of diabetes insipidus is justified in the presence of these two signs; there was evidence in both cases that the complaint was of long standing. The cases are examples of the complaint in its slightest form, since their excretion of urine was not often more than 4 litres in the 24 hours and was some days as little as 2 litres, while the specific gravity of the urine was generally about 1010 in a 24-hour specimen, and sometimes normal, in a single specimen.

The association of diabetes insipidus with pituitary disease has long been recognised. More recently G. L. Kennaway and J. C. Mottram[6] have reported two cases of diabetes insipidus in which there was evidence of pituitary involvement, and in this communication they give an account of present knowledge of the relation of pituitary disease to diabetes insipidus. These observers come to the conclusion that "the existing evidence of morbid anatomy seems on the whole to be distinctly in favour of an association between lesions of the glands and the disease in question." Though disease of the pituitary gland may occur without polyuria there do not appear to be any cases on record in which diabetes insipidus occurred and in which the pituitary was proved post-mortem to be normal, or where it was normal the stalk free from any pressure. Physiological evidence supports pathological evidence on this point. Thus Swale Vincent[7] states that "so far the only symptom of acromegaly which appears to have a direct relation to the function of the pituitary, as revealed by physiological experiment, is polyuria." From the clinical aspect we know polyuria as a frequent symptom in both acromegaly and dystrophia adiposis-genitalis. Neither patient showed any very obvious sign of pituitary disease, but in spite of this, on the strength of the general evidence outlined above, it is justifiable to diagnose both cases as pituitary dystrophies and to inquire particularly for the presence of other signs in support of this diagnosis. Case 1 had an enlarged sella turcica, an enlargement which of itself is not sufficient perhaps to determine a pathological condition, but of importance in relation to the facies (the slight exophthalmos and congestion of the sclerotics) and the general consideration of the case. Case 2 varied from the normal in the direction of acromegaly in the following skeletal features: the lower jaw was underhung, the skull dolichocephalic, and there was dorsal kyphosis; hirsuties was marked.

Both patients made chief complaint of headache and definite complaint of lassitude. This lack of energy is a common complaint in pituitary disease, varying from a feeling of inertia and drowsiness to remarkable periods of somnolence. The headache in both cases was frontal; in Case 1 it was bilateral and in Case 2 limited to the right supra-orbital region. Headache is a constant symptom in pituitary disease. In the cases of pituitary disease described by K. Falta[8] and Harvey Cushing[9] headache is rarely absent. Cushing regards a bitemporal headache as the more characteristic of pituitary disease. At the same time, many of the patients whose histories he gives complained of a severe frontal headache. In our experience frontal headache situated deep in the supra-orbital region, and described by the patient as a tight feeling or gnawing pain, is not uncommon in pituitary disease, and Pardee[10] has lately drawn [illegible]tion to the frontal distribution and in[illegible] headache in pituitary disorders.

There remains for consideration the intermittent glycosuria exhibited by both patients. This glycosuria is in no sense an early phase of diabetes mellitus on account of its slight degree, its intermittent nature, its non-progressive course, and its independence of diet. In neither case did a large carbohydrate meal lead to the appearance of sugar in the urine. The intermittent nature of the glycosuria distinguishes the cases from diabetes innocens, and it is of interest that one of the cases recorded by H. Salomon[11] in his original communication on diabetes innocens complained of polyuria, and did not therefore perhaps belong to his group. Apart from the case described by Mackenzie Wallis and Roper, the only group of cases to which our cases bear any resemblance are the intermittent glycosurias observed in acromegaly. Sir Archibald Garrod[12] has written that the glycosuria in some cases of acromegaly is intermittent "although the patient's diet was by no means poor in carbohydrate." In the same context he notes that "in the newer literature of pituitary tumours, since 1886, Borchard found no record of glycosuria apart from acromegalic symptoms." The chemical examinations of the blood sugar establish the importance of these small traces of glucose occasionally found in the urine in these patients. These researches indicate a lower sugar tolerance in both cases and a lowered leak point in one case, and they further lead to the prospect of new light being thrown on this aspect of sugar metabolism.

In the present state of our knowledge the positive Loewi's reaction observed in Case 2 is to be regarded as an indication of a polyglandular dystrophy, and not necessarily as a sign of pancreatic disease. The association of pancreatic disorder with acromegaly is referred to by several writers (v. Falta), but in our patients there was no evidence of pancreatic disease other than the glycosuria; the diastase reaction was normal in both.

Summary.

The two patients here described appear to be examples of a pituitary dystrophy comparable to those clinical cases of thyroid dystrophy in which there is no marked change in the size of the gland and no distinct clinical picture of either hypo- or hyperfunction. From their past history neither case seems to be progressive, though Case 2 is liable to periodic variations. These patients are not therefore regarded as early cases of acromegaly or other recognised pituitary syndrome, but rather as persons in whom the pituitary is functioning irregularly and perhaps at times excessively. We believe that cases of the type here described have not been previously recognised. The two patients are alike in their salient features, and they do not fit into any of the subdivisions into which Cushing divides his five main groups of dyspituitarism. The interest of the cases does not lie in the possibility of their representing a group of dyspituitarism that has hitherto escaped recognition, but depends on the fact that such cases may lead to the recognition of clinical phases of pituitary activity that bridge the gap between physiological and pathological states. When this borderland has been explored the earliest stages of progressive pituitary disorders will be more easily recognised. Cushing remarks that "it would be precocious to make a diagnosis of 'acromegaly' before enlargement of the acral parts of the body occurs. Still it would be possible." Though our two cases are not regarded as early cases of acromegaly, they do bring nearer the possibility that Cushing foresees.

We wish to thank Dr. Langdon Brown for permission to make use of his observations on Case 1, when the patient was under his care in the autumn of 1919, Mr. Foster Moore for his examination of the fundus oculi of both patients; and Mr. George who gave us the advantage of his special technique in the measurement of the pituitary fossæ by X ray photography. Dr. E. I. Lloyd, house physician, was responsible for the care of the patients and for carrying through the routine of examination. We are indebted to Dr. Drysdale nission to publish these records of his cases.

THE CULTURAL DIAGNOSIS OF ENTERICA IN INOCULATED INDIVIDUALS.

BY J. C. G. LEDINGHAM, C.M.G., M.A., D.SC., M.B., CH.B. ABERD.,

CHIEF BACTERIOLOGIST, LISTER INSTITUTE, LONDON.

THERE appears to be an impression that preventive inoculation against enterica diminishes the chance of recovering the causative organism from the blood. Thus, in a recent paper by R. P. Garrow,[1] entitled "The Myth of 'Atypical' Enteric Fever," with the argument of which I am in sympathy, in substance at least if not in detail, the following statement occurs:—

> "The difficulty of recovering enteric bacilli from the blood of inoculated soldiers is well known, even in the early stages of illnesses which clinically resemble enteric."

Is this a well-known fact? If so, I am not aware of any published data in its support. In bacteriological circles on the Western front during the late war it would appear that a similarly pessimistic view was held. Thus A. E. Webb-Johnson,[2] writing of his experiences at a stationary hospital in France, remarks:—

> "With regard to inoculation there is another point, which is possibly one of the most important. The specific bacteria are not found in either blood, fæces, or urine with anything like the same frequency nor in such numbers as in the non-inoculated, since the microbes are killed more rapidly and effectually, owing to protective substances being in the body ready for the attack."

The fostering of such views gave, I imagine, the impetus to that concentration on agglutination tests which formed such a feature of enteric diagnosis in France. Largely on that basis of diagnosis cases of enterica have been analysed from the standpoint of clinical syndrome, and for some time it has been current teaching that inoculation profoundly modifies the type and severity of the attack in inoculated individuals. With this aspect of the case I am not immediately concerned, but I hold that any comparative analysis of clinical syndrome or of incidence and mortality statistics in inoculated and uninoculated individuals must, to be above all reproach, be founded on a culturally diagnosed series of cases.

Analysis of 373 Cases in American Army.

This has been done in a recently published and most valuable article by the late Major V. C. Vaughan,[3] of the United States Army, whose conclusions are in agreement with those of Garrow (loc. cit.). This author submits with full bacteriological particulars a clinical analysis of 373 cases of enterica (mainly typhoid) which occurred among American troops in France, all of whom had been inoculated with the triple vaccine. For the purpose of his analysis the following proviso was laid down:—

> "No case has been accepted for our statistical study as being undoubted typhoid or paratyphoid fever unless the causative organism has been isolated either from the urine or fæces, or preferably from the blood. I recognise that the finding of the typhoid or a paratyphoid bacillus in the fæces alone does not establish a diagnosis, but have assumed that this finding, together with the presence of characteristic clinical symptoms of the disease and with negative blood cultures, form sufficient evidence on which to base a diagnosis."

A series of 270 cases in which *B. typhosus* was recovered from the blood or excreta (180 by blood culture) is taken for the main clinical study. His conclusions cannot be summarised here, and I need only say that the results of the analysis went to show that vaccination had not altered the essential characters of the disease.

> "The most striking feature of the disease in the inoculated is its almost classical resemblance to the old typhoid as we know it in the unvaccinated. Not only was this resemblance true on paper, but it was likewise true at the bedside."

No convincing evidence was found that vaccination lessened the chance of finding the infecting organism, and in fact Vaughan's positive cultural results from blood, urine, and fæces reached remarkably high figures, as we shall see. Some of the bacteriological data are of great interest, and I propose to consider them in the light of certain data from the Mesopotamian laboratories now published for the first time. Of Vaughan's series of inoculated individuals 274 were submitted to blood culture (repeated if necessary) with a yield of 180 positive results—viz., 143 at first trial, 25 at second, 3 at third, and 9 at fourth. Blood culture was successful in the first week in 65·7 per cent. of trials, in the second in 54·7 per cent., in the third in 46·7 per cent., and in the fourth in 21·7 per cent. The urine was cultured in 109 cases with positive results in 33·9 per cent., and of 270 cases in which the stools were examined no fewer than 193 (70·2 per cent.) were successful. Simultaneous blood and fæces cultures were made on 150 cases in successive weeks of the disease, and the results showed that during the first week the chance of success by stool culture was about two-thirds of that obtainable by blood culture, whereas in the second week the chances were about even. In the third week stool culture gave a somewhat better chance. From the third week onwards the value of both methods decreased. To summarise, Vaughan's series of 373 cases of enterica in inoculated troops comprised 270 cases of culturally proved typhoid, 9 cases of culturally proved paratyphoid A, 23 of paratyphoid B, 12 classified as paratyphoid "indeterminate," and 59 cases of "clinical enteric" which did not yield to bacteriological inquiry. Vaughan's series of 373 cases must be regarded as a very specially observed and repeatedly investigated class, and it is not surprising that the yield of positive isolations reached the high figure of 84·1 per cent. all over.

Blood Culture Results from Mesopotamia.

With the varying conditions obtaining in a wide and scattered front such as we had in Mesopotamia, a figure such as this was not to be expected, but I am quite satisfied that even this figure may be attainable (and indeed was approached) in special circumstances where ward and laboratory act in partnership and all forces are concentrated on the diagnosis of enterica by isolation of the causative organism. I have summarised elsewhere[4] some of the bacteriological statistics in connexion with enterica as met with in Mesopotamia, and I may simply repeat here that we had two classes only of notified enterica—viz., (1) confirmed enterica (isolation of T., A., or B.) and (2) clinical enteric group or E.G. Diagnosis by agglutination methods was not accepted officially and was not practised. During the period October, 1917, to December, 1918, of 1577 cases of notified enterica in British and Indian troops, 734, or 46·6 per cent., were confirmed by the laboratories (1039 British cases yielding 36·9 per cent. of confirmations and 535 Indian cases yielding 56·8 per cent. of confirmations). When all the circumstances are considered the figures are, in my opinion, highly creditable to the Mesopotamian bacteriologists and, as I have indicated, higher figures up to 70 or 80 per cent. were reached in certain hospitals dealing with small but thoroughly investigated series. Now, what facts emerge from a consideration of these cultural results in relation to previous inoculation? From my notes of the Mesopotamian laboratory returns I have abstracted the cases of successful blood culture for the period August, 1918, to January, 1919 (six months). I find that of 139 cases diagnosed by blood culture 78 (viz., T. 22, A. 38, B. 18) were inoculated men, 28 were returned as not inoculated (T. 19, A. 5, B. 4), and 33 were set down as "no pay-book entry" (T. 15, A. 14, B. 4). Thus of the total at least 56·1 per cent. yielding positive blood cultures were definitely inoculated men; 35 had received T.A.B. vaccine in 1918, the year of their attack, 24 had received their last dose in 1917, 17 their last dose in 1916, and 2 in 1915 (probably typhoid vaccine only). There would, therefore, appear to be no justification for the assumption that in a mixed group of inoculated and uninoculated men it is the latter which are most likely to yield positive blood cultures.

Blood Culture and Period of Disease.

One other point may be usefully referred to here. Unsubstantiated statements have been made with regard to the duration of the bacteriæmia in typhoid and paratyphoid infections respectively as affecting the chance of successful blood culture. Accurate data on this matter can be obtained only by a very special investigation involving repeated blood culture in a series of culturally proved cases (by blood or otherwise), and so far such data are not forthcoming. It may, however, be of interest to bring forward certain figures connecting successful blood culture with period of disease in typhoid and paratyphoid infections respectively; I have notes of 102 cases of typhoid, 84 of paratyphoid A, and 26 of paratyphoid B. The results in 4-day periods are as follows:—

	No. of cases diagnosed of		
	Typhoid.	Para. A.	Para. B.
Between 1st and 4th day	11	12	8
" 5th " 8th "	51	46	12
" 9th " 12th "	26	20	2
" 13th " 16th "	8	3	3
17th day and afterwards	6	3	1

Assuming that the great majority of these cases arrived in hospital towards the end of the first week of the disease the distribution in time of the various diagnoses made would seem to show no material difference whether *B. typhosus* or *B. paratyphosus A* was the infecting organism. The figures for *B. paratyphosus B* are too small to be of significance.

Discussion and Conclusion.

Though I am unable to find any support for the assumption that in the inoculated individual who contracts enterica the degree and duration of the bacteriæmia are altered to the consequent detriment of successful blood culture, I must admit the plausibility of the assumption. R. L. Stone[5] has shown that typhoid bacilli injected intravenously into immunised rabbits disappear from the blood and tissues (except possibly the gall-bladder) in 24 hours, whereas in normal rabbits similarly injected bacilli may take ten days or more to disappear. Doubtless in the great majority of inoculated individuals who ingest typhoid bacilli some mechanism of this kind is at work to prevent infection. What part is played in this disappearance by bactericidal bodies in the blood and tissues must be left at present an open question in view of some recent divergence of opinion on the question of increased bactericidal antibody-content in the blood of animals immunised against *B. typhosus*. On the other hand, we must bear in mind that neither in the individual nor in the mass is immunity absolute. Even under the most rigidly controlled laboratory conditions, when large series of animals are taken, no antigen will produce an immunity which protects 100 per cent. of the immunised against a dose which kills 100 per cent. of the controls. The experiments of S. Rowland[6] on immunisation of rats against *B. pestis* may be consulted on this point.

Under actual military conditions, although some approach to constancy of antigen and degree of immunisation may be realised, there can certainly be no constancy of the test dose or of the individual human factor. The results in the rabbit, an animal naturally insusceptible to typhoid fever and artificially educated to deal with *B. typhosus* introduced into its circulation directly, need not, in my view, have their strict counterpart in the vaccinated man who manages to contract by another channel of infection the germs of a disease to which his race is naturally susceptible. In the light of Besredka's recently promulgated views on immunity in enteric infections, the explanation may be found in inefficient immunisation of the intestinal epithelium or in a breakdown of what amount of immunity it may have acquired. The disease would then in all probability proceed on ordinary lines.

Vaughan (loc. cit.) in the search for possible explanations of the occurrence of typhoid in inoculated American troops, makes the following, among other suggestions. The vaccinated person takes into his interior probably large doses of the infecting bacilli, the majority of which he is capable of dealing with. Some, however, may find a nidus in the gall-bladder (as in the immunised rabbit) and there proliferate.

> "The numbers of organisms that are continually discharged in the bile and resorbed through the intestinal mucosa call on the immunity mechanism for constant and exhausting action."

When to this antibody-exhaustion is added the fatigues and hardships of war with its attendant diarrhœal troubles, the chances of an ultimate systemic infection are enhanced. This view, which would attribute a systemic infection to a breakdown of immunity in a carrier presupposes some evidence of intestinal trouble preceding the attack, and in this connexion Vaughan notes that of 104 inoculated men who contracted typhoid fever 60 per cent. had antecedent diarrhœa. It was Vaughan's opinion that two of the chief causes of typhoid fever among vaccinated American troops were (1) the ingestion of overwhelming doses of the infecting organism, and (2) loss of resistance and antibody-exhaustion due to the exposures of military life. It should be mentioned that the majority of Vaughan's cases had received the saline triple vaccine and a minority the lipovaccine. In a non-vaccinated population of all ages the variety of clinical forms in which enteric disease presents itself has long been recognised. Whether in a vaccinated population there occurs a relatively greater proportion of mild cases among the attacked than would be found among the attacked of a non-vaccinated population must be determined on a basis of cultural diagnosis. The practicability of such diagnosis is not, so far as present evidence shows, enfeebled by previous inoculation.

In conclusion I may add that I have been in communication with Sir William Leishman on the question ventilated in this note. Unfortunately it may be some time yet before the relevant data can be extracted from the medical case-sheets and laboratory files of the Western front. Sir W. Leishman informs me, however, that bacteriologists in France certainly supported the views I have attributed to them in the present communication. The question is of high theoretical and practical importance, and the publication of this note may, I hope, stimulate further inquiry.

TREATMENT OF THE CRIPPLING DISABILITIES OF CHILDREN.

BY G. R. GIRDLESTONE, F.R.C.S.ENG.,

SURGEON, SHROPSHIRE ORTHOPÆDIC HOSPITAL; ASSISTANT ORTHOPÆDIC SURGEON, RADCLIFFE INFIRMARY, OXFORD; SURGEON, ORTHOPÆDIC HOSPITAL, HEADINGTON, OXFORD.

What are the main crippling disabilities?—In every list of cripple children, whether compiled in this country, in America, or on the Continent, three main groups constitute the bulk, and do not vary much in their proportions: (A) Deformities congenital or acquired; (B) paralyses; (C) tuberculosis of joint and bone. Of 1130 cases under treatment in Shropshire and North Staffordshire in 1919, and listed in Birmingham in 1911, there were: Group A, 35 per cent.; Group B, 32 per cent.; Group C, 28 per cent.; various, 5 per cent. Of 12,496 cripple children of whom the writer has been able to obtain particulars, in 35·4 per cent. the crippling disability is *non-pulmonary tuberculosis*, and in 52·5 per cent. it is of the A or B group. The total number to be dealt with is very large; the inquiries as to cripple children, quoted in the report of the chief medical officer of the Board of Education for 1919, give returns averaging 8·6 per 1000 school population, and it is clear that many of these returns are incomplete and give only a fraction of the true proportion.

Is there failure in the treatment of these disabilities?—At present the failure is exceedingly great: the prin- asons are as follows: (1) the cases do not, as a t into touch with efficient treatment early enough; (2) many of the cases never get efficient treatment at all; (3) a great majority of the cases suffer for lack of after-care. Every neglected congenital deformity, every "hump-back," every joint deformity due to infantile paralysis, indeed, the great majority of all cases crippled by this disease, are examples of one or other, or even of all, of these failings.

Is the present system to blame?—There is no system! It is the absence of any organisation, even of any general agreement as to organisation, that makes the treatment of the child threatened with crippledom so ineffective. Some cripple children go to the union infirmary and stay there; they often have no education, and generally no treatment unless they are acutely ill, and then often only for a short period at the nearest general hospital. These are not imaginary statements; they are based on common findings of the inquiry carried out by the Central Committee for the Care of Cripples. Some go to special hospitals for non-pulmonary tuberculosis, but, as a rule, only when they are definitely suffering from established tuberculous arthritis. To quote from a recent discussion by specialists in another sphere: "The specialist sees the difficult cases and the failures." Surely many cases of early tuberculous disease become difficult cases and lead to permanent crippledom merely because of lapse of time. That is typical of the failure of the present chaotic arrangements.

Typical Cases of Failure in Treatment.

Take an early case of *tuberculous hip.* A child develops a limp and cries at night. His mother knows, possibly the district nurse knows, perhaps he is even taken to the doctor. A limp and a cry or two, and for physical signs just limitation of movements of the joint in all directions, with a little flexional deformity from muscular spasm. There is no apparent sign of urgency. But actually there is *no time to be lost.* Prompt immobilisation of the affected joint, a bed in an open-air ward, and good feeding will prevent suffering, and will almost ensure, in perhaps nine months, full recovery, often without any permanent disability.

But only very few of these cases actually find their way into hospitals for tuberculous joints at this stage. The golden opportunity slips by, there is uncertainty, then delay, and the disease tightens its grip! Suffering and illness increase, the text-book picture becomes easily recognisable, the joint surfaces are destroyed, there is danger to life, treatment is now not a matter of months but of years, and the child at best will be a cripple. Actual instances without number can be given of children who have paid by their prolonged suffering and illness, their joint destruction and permanent crippledom, the extreme and needless cost of our present lack of means for early ascertainment and facilities for immediate treatment.

Take *infantile paralysis.* A child is feverish, perhaps very ill. One or two limbs seem powerless; the child is restless, in pain, and cries if touched. Perhaps some weeks later he is brought to a hospital and there given "massage and electricity" for a few weeks, or, if the child lives within out-patient reach, for months or years. Much recovery may occur even with this late and ineffective treatment, but the number of children needlessly crippled by preventable paralysis is very great. The profession as a whole has by no means yet realised the principle of ganglion cell rest as an urgent measure in the first stages of this disease, whether the onset of paralysis is associated with a feverish illness or not.

By the immediate immobilisation of the head, spine, and affected limbs, with correct posture[1] and undisturbed skin protection, the inflamed or poisoned cells are given the functional rest they need and cannot otherwise get. We know that even without that rest much recovery takes place (quickly or slowly); it is then reasonable to assume, as, indeed, Mackenzie's cases tend to prove, that with proper spinal and neuromuscular rest the recovery will be quicker, more extensive, and more often complete.

---

[1] William Mackenzie: The Treatment of Infantile Paralysis, Melbourne, 1910; Robert Jones, THE LANCET, May 30th, 1914.

A *congenital deformity* is, of course, not quite so urgent a matter, but, none the less, the ultimate result is far better and can be obtained more quickly, with less disturbance and less pain, if the defect is treated as soon as it can be detected.

Scoliosis and other deformities which develop insidiously are also at first treated easily, later with difficulty or with only partial success.

In every branch of the work early treatment tends to prevent crippledom, to forestall illness and suffering, and to eliminate the need for operation.

It has been stated that some cripples never get efficient treatment at all. How is this? It is due to lack of suitable provision for their needs, for the work cannot be done on an adequate scale by the general hospitals. The cases are slow and tedious; they need a country hospital with open-air wards, splint and appliance workshops, educational facilities, and so on. Means must be available to ensure the accurate fit and comfort of a splint, frame, plaster, or appliance, and workshops where these various needs can be supplied quickly for each case, to the exact specification and under the superintendence of the surgeon, are of the very greatest advantage. General education and handicraft training are required for these children while in hospital, for otherwise many have no teaching for very long periods, and thus have an educational as well as a physical handicap. The joint consideration and proper coördination of treatment and education is very important.[2]

Again, in these cases there is no natural convalescence. Operations, manipulations, and even prolonged retention in hospital do not finish the treatment. Without thorough after-care deformities will inevitably recur, club-feet, though over-corrected, will relapse, posture, gravity, and uneven muscle-balance will cause deformity in cases of infantile paralysis, and tuberculous hips will insidiously change abduction into adduction.

To sum up, failure is due to want of (1) early treatment; (2) efficient treatment in suitably sited, equipped, and staffed hospitals; (3) thorough after-care.

A Proposed Scheme.

Outlines of a proposed national system to meet these needs have been worked out by the Central Committee for the Care of Cripples as follows:—

I. A central coördinating body which should work with the Ministry of Health and the Board of Education.

II. Local committees for the care of cripples in every district.

III. Hospital schools. The provision in England and Wales of an adequate number of hospital schools for crippled children with open-air wards.

IV. Each hospital school should be run under its own local committee, with its own teaching staff and handicraft workshops. Working in direct union with the hospital school should be:—

(*a*) Out-patient clinics for—(1) The examination of children sent up for consultation; (2) the treatment of cases which can be effectively treated as out-patients; (3) the after-treatment and supervision of children discharged from the hospital school; (4) the maintenance of touch with old patients so that advice and help may be given as to suitable employment.

(*b*) Invalid schools, day and residential, for the minority of children who have not been cured or benefited sufficiently to enable them to attend ordinary classes. In large towns special day schools will fill the need; but for children in other districts, who are prevented from receiving education by their persisting disability, residential schools are necessary. For the sake of simplicity and economy these should be part of the establishment of the hospital school, but in a separate wing. These children would be drafted into this when fit to leave the hospital, but would continue to benefit from the teaching, handicraft shop, and surgical supervision.

V. It is vital that those responsible for the treatment should be experienced in orthopædic work. This applies both to the surgical staff and the hospital and after-treatment sisters.

VI. There should be provision for paying patients.

VII. Wards should be available for adolescent and adult cripples and persons suffering from injuries needing orthopædic treatment.

VIII. Where efficient organisations for crippled children exist these would be welcomed in the scheme which should be sufficiently elastic to cover some diversity of method.

The essential principles of the proposed scheme are those already stated, and aim at treatment, very early, very efficient, and very complete.

The suggested hospital and clinic organisation is developed from an existing unit which has been doing this work in a county area for a good many years. There the organisation was gradually developed to meet the difficulties already mentioned, the tragedy of children coming into hospital with established disease, deformity, and paralysis, and of others readmitted with relapse owing to the impossibility of keeping touch with all discharged cases, of whom many live at considerable distance.

Hospitals for Cripple Children.

The essence of the system is the establishment of hospitals for all types of cripple children to serve a more or less definite district—say, one, two, or three counties; hospitals which should accept responsibility for every cripple right through the district, organise team-work, and enlist in the team every doctor and every health worker. Success depends on a true spirit of coöperation.

Scattered orthopædic clinics.—The working of scattered orthopædic clinics is described in a leaflet used in connexion with the organisation of clinics in another district.

After describing the work of the children's section of the hospital in the treatment of all types of crippled children this leaflet goes on to say:—

> "But, if the hospital is to do its work well, it must achieve not only early treatment but also thorough after-care. Everyone is familiar with patients who have suffered from one or other of these conditions, have had a period of hospital treatment, have apparently been put right, but two years later have been just where they were before, solely as a result of deficient after-care. The very great majority of children are able to become out-patients while still in plaster-of-Paris or wearing appliances. The renewal of the former, and the upkeep, readjustment, and replacement of the latter mean constant work, and at the same time careful watch must be kept for any sign of relapse. This work must fall to the lot of the hospital staff who have carried out the active treatment, and have the enormous advantage of a workshop where any repair, alteration, or renewal of appliance or boot may be done quickly and to the exact requirements of the surgeon.
>
> It was for this after-care, which has to be kept up for years, that the local orthopædic clinics were started in connexion with the Shropshire Orthopædic Hospital, for it was found quite impossible to bring all the old cases up to the hospital frequently. Their practical value was quickly and abundantly proved. Here a number are already working, and it is proposed to set them up throughout the area served by the hospital—i.e., principally Berks, Bucks, and Oxon.
>
> In starting a clinic a suitable centre, generally a market town, is chosen, the county medical officer of health and the local doctors are consulted, so that, if possible, it may be held in the cottage hospital or in rooms which are used for infant welfare or other health purposes. Representatives of the B.R.C.S., Infant Welfare, Nursing Federation, or other voluntary associations are asked to form a local committee to run the clinic, help in its work, contribute to the expenses, and act as almoners. This committee might well become a branch of the Invalid Children's Aid Association. Sisters specially trained in orthopædic work visit the clinics, which are held every week or every fortnight, according to the need. They see the children coming from the surrounding district and patch or renew their plasters, make sure that their appliances and boots are effective, and so on. These after-care sisters live at, or near, the hospital, and follow closely the treatment of any cases from their districts which are in the hospital, so that there may be no break in continuity of purpose. The sisters never initiate treatment, their work is to carry out the treatment ordered by the surgeon. The latter visits the clinics to see all the cases once every eight weeks, and makes a special additional visit when necessary. Children who are not actually sent up by their doctor are referred to him before their treatment is commenced. A list of the regular visits of the surgeon is sent to the doctors in the locality, who are thus brought into touch with the work of the hospital, and can readily refer cases for treatment or consideration. They can keep in touch with a patient right through, for they are always very welcome at the clinics or the hospital.
>
> This coöperation is really an extension of team-work, and means much to all concerned. To the hospital it means the possibility of early treatment and thorough after-care; to the doctors it is helpful in that, otherwise, the management of cases requiring much plaster work, all sorts

---

[2] The Care of Cripple Children, Brit. Med. Jour., May 22nd, 1920.

of apparatus, special boots, &c., is difficult and troublesome; to public health representatives it is valuable, as the work concerns, mainly, children for whose treatment they are responsible."

This system has proved completely successful. Cases are now sent to the local clinics or the hospital in the early stages; this change is progressive, as the parents, doctors, school medical officers, nurses, health visitors, &c., realise more and more fully what is being done for the various conditions and the importance of losing no time; and the after-treatment is carried on till all danger of relapse is past.

To the doctors the clinics are a great help. The cases treated need plasters and appliances often for very long periods, and these require constant care, alteration, or renewal, work practicable when one is always at it and there are hospital workshops at one's elbow, but in private practice or for a general surgeon almost impossible. Perhaps the commonest cases attending the clinics are those of past acute poliomyelitis with resultant paralyses and deformities. In a young child there are years of treatment by plaster and appliances ahead: first, the correction of deformities and the prolonged postural treatment of the muscles; then the consideration as to further measures to restore lost muscle function, or to stabilise joints. And often there is a time of waiting until the child reaches an age when an operation which is required can best be carried out. It is, for example, disadvantageous to do an arthrodesis until the subject is about 8 or 10 years old. Sir Robert Jones has said: "There is plenty to be done during the waiting, and if this be done well perhaps no operation will be needed."[3] Even long-neglected cases of this disease often show astonishing improvement when paralysed muscles are treated by constant relaxation for long periods with simple re-education.

All this work is difficult and tedious and hardly practicable except by means of local clinics. They are really extensions of the hospital out-patient department, and serve to bring the hospital within easy reach of the parents and the doctor. A frequent long journey with a cripple child is quite impracticable for most working-class parents who have a house and perhaps other children to look after. Unless a clinic is available within a reasonable distance of their home they sooner or later fail to bring the child up for treatment or supervision.

Early ascertainment.—A deformity or the warning sign of a crippling disease may be noticed first by a doctor, a midwife, a school medical officer, or infant-welfare worker. It is evident (1) that all these people must appreciate the importance of immediate action; (2) that ready means of getting the cases to hospital or clinic quickly must exist. It is only by the actual intercourse between hospital staff and primary health workers affected by the district-working hospital and its clinics that the necessary knowledge is attained and facilities for prompt diagnosis and treatment provided.

The problem in big cities.—In London and other big cities the problem is analogous, and can be solved in the same way. Instead of one central hospital school there might well be institutions of similar type in the country attached to orthopædic hospitals or orthopædic departments of general hospitals. Instead of a large rural district with a population a quarter or half a million, a district of the town of somewhat similar population might be assigned to each unit. The hospital would be responsible for working its district on lines which would ensure early ascertainment, continuity of treatment, and thorough after-care.

Finance.

Establishment of hospitals.—Total new construction will often be avoidable. Many suitable or adaptable hospitals exist, either already devoted to work of this type, old military hospitals, or those still in use by the Ministry of Pensions. Where new building is necessary it should be of a simple type, and have the twin virtues of low establishment and low maintenance costs. Such a hospital has been described elsewhere.[4] It should be of semi-permanent construction, for even so it may outlast its author's generation, and eventually be considered quite out of date and ineffective. Establishment grants from the Ministry of Health are available for the proportion of beds devoted to non-pulmonary tuberculosis.

Maintenance.—If the hospital school is "approved" by the Board of Education and by the Ministry of Health the maintenance costs can be claimed from the local authorities responsible for each case, provided they authorise the admission. The authorities can collect what is fair from the parents, and can demand from the Ministry of Health and the Board of Education 50 per cent. of their own expenditure. The average weekly hospital expenses can be divided by the number of in-patient children. The sum thus arrived at can be charged to the authorities; the charges for cases coming under the education authorities must first be approved by the Board of Education.

The responsible authorities are: (1) For all tuberculous cases and for all children under school age, the local public health authority; (2) for children of school age (non-tuberculous), the local education authority.

Conclusions.

1. There are a great many cripple children in this country and a still larger number of adults whose crippledom dates from childhood.

2. Most of these cases need not have been permanently crippled if they had been given adequate treatment at an early stage of their disability.

3. Of cripple children, about one-third suffer from non-pulmonary tuberculosis, and about two-thirds from other crippling conditions.

4. The need for the adequate provision of treatment for these disabilities is very great; it has been recognised and provided for by legislation.

5. Unless a coördinated and comprehensive policy is adopted there will be a muddle—in some places a good scheme, in others a bad one, in others, again, for a long time none at all.

6. For the treatment truly to meet the need it must be (*a*) very early, and so largely preventive; (*b*) efficient in suitably sited, equipped, and staffed hospitals; (*c*) completed by thorough after-care.

7. Very early treatment and thorough after-care can only be achieved by a hospital centred in a "district," and responsible for working that district by coöperation with other health workers.

8. Every area in the country must be served by a hospital for cripple children.

9. The special hospital conditions necessary for the various types of crippling disease, paralysis, or deformity are almost identical. A hospital satisfying the needs of the tuberculous cripple will provide all that the others require. The "local clinic" organisation is needed for all types.

10. In certain places hospitals for all varieties of cripple children already exist. Several already have a local clinic system; in others it is as yet undeveloped. In one district, where the organisation has been working for some years, the results have been most satisfactory.

11. In any district where there is a hospital for non-pulmonary tuberculous cases, and no provision for other types, that institution should enlarge its scope. To set up a separate hospital and clinic organisation for the non-tuberculous cripples would be foolish and extravagant; to leave them without provision a great deal worse.

12. The hospital which exists to deal with cases sent from a distance, with arthritis deformity or paralysis established, will become a thing of the past. Such hospitals have done magnificent work, and have been the honoured teachers of us all; but the treatment of crippling disabilities is becoming more and more of a preventive nature.

13. The establishment of this system of treatment means to substitute early and thorough treatment for what has hitherto been tardy, difficult, costly, and incomplete.

14. The expense will now be definitely associated with this treatment instead of hidden in a mass of other work, but it will be justified on economic grounds alone; many who would otherwise be sources of loss will thus become earners and producers.

OSTEITIS DEFORMANS?

BY FRANK ROMER, M.R.C.S. ENG., L.R.C.P. LOND.

With Observations by SIR W. ARBUTHNOT LANE.

IN the very clear and full description of osteitis deformans given by Sir James Paget, based on his observations of many cases, two points stand out—namely, the subsequent affection of the skull and other long bones and the comparative freedom from pain. I have had the opportunity of closely observing in the last four years the progress of an osteitis affecting the tibia, which from its likeness to Paget's disease caused many of us to regard it as such. Lately, I have come across cases showing deviations similar to the classical description of Paget's disease, which have caused me to wonder if there are not two distinct types of this condition.

Symptoms often differ in many well-known diseases without affecting the diagnosis, and I am writing this paper in the hope that other observers may have come across cases which, while resembling Paget's disease in certain particulars, show similar differences to the cases I propose to describe. The operative treatment, undertaken at my request, will be detailed by Sir W. Arbuthnot Lane; not only did it give instant relief to the pain, but was followed by the formation of healthy bone.

Three Cases Described.

The first case was that of a healthy man, 44 years of age. In June, 1915, he was descending a ship side in a rough sea by means of a Jacob's ladder. The drop was deeper than anticipated, and in landing he struck his right tibia on the gunwale of the boat. The pain at the time was exasperatingly severe, but passed off shortly; the shin, however, remained painful to the touch for about a month. In October a slight enlargement of the tibia became noticeable, together with a sensation of itching, unrelieved by scratching, as it appeared to be in the bone itself. The sensation of itching drew the attention of the patient to the small enlargement. A radiograph showed a small patch of osteitis. The patient had never suffered from syphilis, and subsequent blood-tests eliminated this as a possible factor. The patient ignored the condition till December, 1917, when the steady increase of pain and ensuing lameness, combined with the obvious enlargement of the upper end of the tibia, caused him to ask his colleague at Millbank Hospital, the late Dr. Cecil Lyster, to radiograph the limb. The radiograph showed the whole upper third of the tibia to be affected by an osteitis. By the advice of Dr. Lyster iodide ionisation was tried, but with no result.

Œdema was present over that portion of the tibia affected by disease. The pain varied from a dull ache to acute lancinating pains, running down the shaft of the bone. Exercise and such things as the vibration caused by railway trains or a motor-car increased the pain, which, like all bone pains, was invariably worse at night. To be roused at night by cramp in the calf of the affected limb was of constant occurrence and after the muscular spasm had passed off the bone would ache for hours. Pressure or light tapping during examination of the leg invariably set it aching. Rest might possibly have given relief, but the patient was attached to various military hospitals necessitating daily travelling, so was unable to lie up.

As the pain and lameness were affecting the patient's well-being it was decided to try the effect of an operation. This was done in February, 1918, and by the end of March the patient was about on crutches attending the surgical gymnasium at Millbank for special exercises. At the end of a month's sick-leave all pain had gone and he could walk without difficulty. In May he returned to duty and continued free from pain till the end of July. Towards the middle of that month the sensation of itching had returned in the middle third of the tibia and pain gradually took its place. A radiograph was taken and it was seen that the area of operation was filling up with healthy cancellar bone; the middle third, however, was showing signs of further osteitis. The pain and subsequent disability became so troublesome that the patient applied for a board and was invalided from the Service. Since the first operation had proved so successful it was decided to clear out the diseased portion in the middle third, and this was done in January, 1919. The subsequent history was much as after the first operation, and a radiograph shows healthy bone replacing the diseased area.

There has since been a return of pain in the lower third, but no definite osteitis can be detected at present. The patient gets about on a crutch stick, and, provided no undue strain or use is given the leg, suffers but little, and then only in the lower third. It is hoped that in the course of a few months' comparative rest he will be able to get about normally; but should the disease show definite signs in the lower third he will unhesitatingly have a further operation. Radiographs of the skull and other bones show no signs of disease. Cultures were made from the debris and found sterile, whilst microscopical examination merely showed the normal abnormalities of osteitis.

In another case, that of a lady, there is a definite history of trauma in which she struck her shin against the edge of a punt some 20 years ago. Within a few months enlargement of the upper end of the tibia was noticed, and the patient complained of severe pain. Radiographs taken at this time are singularly like those in the first case. The patient complains of cramp at night, and any attempt at walking causes so much pain that she scarcely attempts to get about. The tibia is now very thickened and bowed. No other bones have been affected. Operative treatment has been advised.

In a third case enlargement of the right side of the lower jaw followed a blow. The osteitis was limited to that portion of the lower jaw, and no other bones appeared to be affected.

Discussion.

The question arises whether these cases are merely a variation of Paget's disease or whether they are entirely distinct. In all three cases the cause was definitely traumatic in origin, whilst in true Paget's the origin is obscure and injury not mentioned as a factor. In the first two cases a period of 5 and 20 years respectively have elapsed and no other bones have become involved. This is distinctly against the normal course of osteitis deformans. Pain, which is practically negligible in the cases described by Paget, in all three cases under discussion has been severe. In fact, were it not for the pain the enlargement of the bone would cause no inconvenience.

The value of operatic interference has been so manifest, followed as it was by freedom from pain and growth of healthy bone, that one wonders whether similar operations would arrest the progress of the more ordinary type of osteitis deformans.

Observations by SIR W. ARBUTHNOT LANE.

At the first operation the inner wall of the tibia was removed along the upper two-thirds of its length. The structure of the tissue removed did not differ in any way from that with which one is familiar in osteitis deformans. On the second occasion a similar operation was performed upon the lower third of the shaft of the tibia.

I have seen several cases practically identical with this, in which in most cases the tibia, but occasionally some other bone, has taken on this condition, the adjacent bones being only affected when the changes in the ends of the diseased bone necessitated corresponding mechanical alterations in the bones with which they are articulated. Most of the discomfort or pain is due to the implication of the joints in the infective process. They all gave a history of a traumatic origin.

I see no reason to call the condition osteitis deformans since its clinical history is quite distinct.

Reviews and Notices of Books.

A CONSULTING SURGEON IN THE NEAR EAST.

By A. H. TUBBY, C.B., C.M.G., F.R.C.S. Eng. London: Christophers. 1920. Pp. 279. 15*s.*

IN 1915 the Army Medical Department decided on the appointment of consulting medical officers to serve with the A.M.S., and Mr. Tubby was one of the surgeons to whom this important post was offered. He received the offer on June 12th, 1915, and on June 20th was on his way to Egypt via Malta, where two of his colleagues were to be landed. Mr. Tubby had a wide experience; he served first in Alexandria, then at Imbros, Mudros, and the Gallipoli peninsula, then in Egypt again as consulting surgeon at Cairo; he was then sent back to Alexandria, visited Khartoum, and finally went to Palestine. In all these spheres he did varied and valuable work, and the book before us is a modest and unassuming record not only of his own labours, but incidentally of those of others. Like many another account of medical matters during the war the feature which strikes us most is the extraordinary powers of organisation and forethought which must be attributed to Sir Alfred Keogh, the Director-General, though it must not be forgotten that he was often served by excellent subordinates.

Mr. Tubby's account of the Gallipoli campaign is sad reading in so far as regards the sufferings of the troops, but it fills the reader with pride in his nationality. The camp at Cape Helles was anything but sanitary, despite all efforts to keep it so, and dust, flies, and lice—especially the last—tried the troops severely. Mr. Tubby quotes the simple remark of a captain, "Here am I, Lord —— and ——, with one hundred and fifty thousand a year and ——lousy." After the heat, the cold. In November, 1915, a sudden storm of rain at Gallipoli was succeeded by two nights' severe frost, and many cases of frost-bite occurred, some leading to amputation, especially amongst the Ghurkas. Possibly the most interesting part of Mr. Tubby's book is that dealing with the Palestine campaign—not that he ventures upon military details, but he gives various little touches which are very real. Thus he describes how when the railway from Egypt into Palestine was being made, the old road—the road that goes back to the ancient Kings of Egypt—was still employed. Progress was naturally slow and toilsome. Some unrecorded genius proposed laying down ordinary wire-netting on the sand to make a track, and this not only made marching easy, but afforded an excellent roadway for motors. The chapter called "The Consulting Surgeon in War" contains much valuable information and suggestion, and altogether the book is well worth reading.

INTESTINAL AUTO-INTOXICATION.

Contribución al Estudio de la Auto-intoxicación Intestinal. By C. J. DIAZ, Professor of Clinical Medicine, University of Madrid. Madrid: Hermanos Ruiz. 1920. Pp. 144. 3.50 ptas.

THIS is a concise and excellent little work of its kind and, coming from the pen of a distinguished author, will be perused with the attention and interest it well deserves. It is partly a compilation from, and commentary upon, the researches of other workers in the field of intestinal auto-intoxication, and partly an exposition of the writer's own views and experience of the subject, which are supported by clinical notes of nine cases under his observation. A large amount of contemporary literature is introduced, with comments, especially that of Lane, Hurst, Herter, Cammidge, Wells, Mellanby, and others in this country, and Combe, Schmidt, and Strasburger on the continent. The author criticises the methods of research into the mechanism, physiological and pathological, of fermentation and putrefaction, the action of toxic products formed in abnormal intestinal processes, and [illegible] absorption of lipoids. He considers that there [illegible] factors to be taken into account in eluci- [illegible] problems of intestinal auto-intoxication, the one corresponding to the chemical substances generated, the other following physical factors, and that the means which are at our disposal for coprological chemical analysis are sufficient to give a good general guide as to the processes which take place. The intestinal flora is as yet little understood, and the functions of certain micro-organisms are twofold, which detracts from the value of methods which rest exclusively on their identification. The author agrees with Oshima that the presence of dissolved albumin in the stools indicates lesion of the mucosa, and that intestinal putrefaction may occur without albumin in the dejecta, and he admits the existence of a dyspepsia, or rather a dystrypsia, from putrefaction in opposition to the "fermentative" of Schmidt and Strasburger. He considers that the fatty acids when absorbed are capable of producing symptoms of themselves, and not through withdrawal of alkali, and that, with the exception of indican, the exact quantity of sulpho-ethers in the urine has no significance. He conceives a "proteinæmic diathesis" which takes the place of the classical arthritism, and explains the transient hypertensions of the constipated by distension of the colon. There are several misprints, which do not, however, detract from the value of the book, such as animo-acids for amino-acids; this occurs several times.

A NATURALIST ON LAKE VICTORIA.

With an Account of Sleeping Sickness and the Tsetse-fly. By G. D. HALE CARPENTER, D.M., B.Ch., Uganda Medical Service. London: T. Fisher Unwin. 1920. With 2 coloured plates, a map, charts, and 87 illustrations. Pp. 332. 28*s.*

IN 1910 Dr. Hale Carpenter went to the north shore of Victoria Nyanja (not Nyanza as it is usually written; the author states that Nyanza "means nothing"). His object was to investigate the bionomics of the tsetse-fly, *Glossina palpalis.* The book is an attempt, and we think a successful and interesting attempt, to give an account of the life on the islands of the Victoria Nyanja, and of that group of islands lying at the north-west of the lake just south of the Equator. The author is primarily an entomologist, so that the chief interest centres round his observations in regard to insects. There are extensive observations on coloration of insects, illustrated by two coloured plates of model species of Planema with mimetic forms of *Pseudacræa eurytus.* The chapters on mammals, birds, and reptiles are confessedly not so ample. In the short space of not quite three years the author accumulated a wonderful body of observations of island life, and as Professor Poulton remarks, the observations recorded "are both loving and accurate." Apart from the earlier chapters on the Natural History of Sleeping Sickness, the most important, according to Professor Poulton, are those which add to our knowledge of *Papilio dardanus*, and the breeding experiments which brought final confirmation to the conclusions that the wonderful series of mimetic butterflies are forms of a single species—*Pseudacræa eurytus.* It appears that the African butterflies include what are probably the two most remarkable examples of mimicry in the world—*Papilio dardanus* and *Ps. eurytus.* To the purely medical reader the chapters which tell the story of sleeping sickness in tropical Africa will be the most attractive. The author concludes that in order to exterminate sleeping sickness the animals must be kept from each other—the Situtunga antelope from which the fly obtains the trypanosome, and the fly which inoculates the Situtunga with the trypanosome. To the naturalist proper the careful and many new observations on the coloration of insects and allied subjects and the discussion on mimicry will perhaps prove the most attractive part of the book; nor must the entrancing account of the doings of the totally blind reddish ant, the Dorylus or "Safari Ant," that lives entirely by hunting live prey, be forgotten.

Altogether, Dr. Carpenter's sojourn on the islands of Lake Victoria has yielded interesting results for the naturalist, and his written record of his work, his voyages by canoe, and descriptions of the scenery make the printed account pleasant as well as profitable reading, even to one not deeply versed in zoological lore.

DIABETES IN INDIA.

Being a Collection of Reprints from the *Indian Journal of Medical Research*. By D. McCAY, Major, I.M.S., Professor of Physiology, Medical College, Calcutta, and Others.

THE prevalence of diabetes mellitus in India is well known and presents a vast problem, which will require many years of detailed work before a solution is reached. The Imperial Indian Research Fund has wisely devoted funds for the purposes of the investigations recorded in the papers, and the authors of this contribution are to be congratulated on the results of the expenditure of much time and labour. A large number of interesting facts have been revealed. The first paper deals with the sugar in the blood and urine in the Bengali. The sugar in the blood of the normal Bengali is found to be 0·13 per cent., a much higher figure than that obtained in the normal average European, and largely explained by differences in the carbohydrate content of the diet in the two races. This excess of sugar in the blood leads to the deposition of fat, and eventually to glycosuria. The sugar tolerance of such individuals becomes lower and lower as the percentage of sugar in the blood increases and with the rising body-weight. Each individual, however, possesses certain narrow limits within which his blood-sugar concentration varies, as also the concentration of blood-sugar at which the kidneys begin to excrete sugar in abnormal amounts. It was found in examination of the urine of the Bengali that the well-known tests often gave indefinite results, and this was especially true of Fehling's test. This is not surprising when quantitative estimations reveal the normal variations of sugar in the urine as between 0·015 and 0·15 per cent. Further, there was no parallelism between the sugar in the blood and that in the urine in people of normal health, in those suffering from a-glycosuric diabetes, in different individuals suffering from varying degrees of glycosuria, or even in the same individual. The authors are of the opinion that the predisposing cause of glycosuria is a gastro-duodenitis leading to an exhaustion or actual inflammation of the pancreas and a disturbance in the internal secretion of that organ. The march of events leading to glycosuria as conceived by Major McCay is given in tabular form, and expresses very clearly his main conclusions.

The most interesting paper in the whole series relates to the causation of death in diabetes mellitus as met with in India. There is no evidence of actual ketosis, and the onset of diabetic coma (air-hunger) as met with in England. On the contrary, the patients almost invariably die of uræmic coma. This uræmic coma is the result of the functional derangement of the kidneys brought about by the continued passage of large quantities of sugar over a prolonged period. The onset of this type of coma is not necessarily dependent upon a definite pathological lesion of the kidneys. The whole of this work is unfortunately lacking in complete proof owing to the absence of post-mortem records—an insurmountable difficulty in the present social and caste conditions in India. However, numerous analyses of the blood are given to support this important conclusion. The last paper deals very thoroughly with the treatment of diabetes in India. One is struck with the ease in which a more restricted dietary removes the glycosuria even in severe cases. This is partly explained by the fact that diabetes mellitus in India is of a mild type, and differs from the severe form as met with in England, where death is due to true diabetic coma. Again, reduction of the carbohydrate in the diet does not lead to ketosis, and diacetic acid is rarely found. As early as 1913 the plan of inducing a raised glucose tolerance by gradually increasing the carbohydrates was adopted. This in essentials was the same plan of treatment as that devised by F. M. Allen, and worked out quite independently by McCay. The difference was that starvation as advocated by Allen was not ordered, simply because it was quite unnecessary in the treatment of the mild type of case met with in India. The observations recorded in these papers are of great interest, and the authors are to be congratulated on an excellent piece of work. That difficulties were overcome and such good results obtained reflects great credit on Major McCay and his stimulating influence on those working in his laboratory.

CHILDREN'S DREAMS.

By C. W. KIMMINS, M.A., D.Sc. London: Longmans Green, and Co. 1920. Pp. 126. 5s.

As Dr. Kimmins points out, little attention has been paid to the dreams of normal people since the psycho-analysts first applied their methods to this subject. Freud's *Traumdeutung* is based mainly on the dreams of his psycho-neurotic patients; and the gradually recognised importance of the study of dreams during the past six years has been due to their value in the exploration of the minds of those suffering from the psychoneuroses of war. In Dr. Kimmins's book we have a collection of dreams obtained from nearly six thousand children of various ages (from 5 to 16), in elementary, central, and secondary schools, in industrial schools, and in schools for the blind and deaf. The conclusions drawn from this important and fascinating study throw a vivid light on the inner lives of children (e.g., the elder girls' fear of strange people), on their waking desires as fulfilled in dreams (children in industrial schools have more idealistic and exciting dreams than children whose lives are more fortunate), and on the changes in the dream content with differences in age and sex, and with deafness and blindness. The dreams of the children of eight years of age and over were recorded by themselves, and it is interesting to note that their power of graphic description of their dreams "so far exceeds their ability in ordinary essay writing on topics selected by the teacher ...... that it would appear as if some fresh mental element had come into play." The matter is, as Dr. Kimmins observes, worthy of further investigation.

DIRECTIONS FOR A PRACTICAL COURSE IN CHEMICAL PHYSIOLOGY.

Fourth edition. By W. CRAMER. London: Longmans, Green, and Co. 1920. Pp. 138. 4s. 6*d*.

THIS excellent and concise handbook has now reached its fourth edition—a sufficient recommendation of utility. The book is small and its scope is necessarily limited, but it embodies most of the recognised tests in general use, as also the practical demonstrations, and it is specially designed for medical students possessing only an elementary knowledge of organic chemistry. The tests for various substances in the blood, gastric contents, urine, &c., are clearly set out, and particular attention is given to the small technical details which are so essential for the successful application of such tests. A pleasing feature of the book is the array of questions which accompany certain tests, as also the excellent notes pointing out the fallacies of the tests. The author is to be congratulated on the demonstration of coagulation of the blood, the description of which is clearly and concisely put. The student is given a clear insight into the phenomena of coagulation without the use of a cumbersome and meaningless terminology.

The importance of the maintenance of acid and base equilibrium in the body is also dealt with in a separate chapter at the end of the book, and a difficult subject is made quite clear by the presentation of several tests and demonstrations. The book should appeal to the general practitioner, especially that part dealing with pathological metabolism. The tests described can be carried out without the necessity of elaborate apparatus or a well-equipped laboratory. The description of acetone bodies in the urine and the tests for their presence is well done and in accord with modern views. The author introduces his own test for the detection of sugar in normal urine, but omits all mention of Benedict's test, which is far superior to some of those described, and should be used in preference to that of Fehling. The book is of small size, and from its undoubted excellence, apart from its price, is to be recommended as a laboratory manual.

MEDICAL EXAMINATION OF AIRMEN.

By Dr. MAUBLANC and Dr. RATIÉ. Translated by NORMAN BALL, M.R.C.S., L.R.C.P. London: John Bale, Sons, and Danielsson, Ltd. 1920. Pp. 88. 5*s.*

THIS little book in its original form was intended as a practical guide for use in the examination of members of the French Air Service and its recruits. Wing Commander Martin Flack contributes an introduction to the English translation without discussing French methods at any length. The authors state that their methods were applied in systematic fashion to every recruit as well as to pilots who arrived from other sections and to applicants for rest-leave, but it is, unfortunately, not very easy to glean from the text complete details of this systematic examination. They express the hope that the book will help the practitioner who may, without previous experience, suddenly be called upon to act as doctor to a flying squadron. In England, at any rate, such a condition is not likely to occur now that systematic courses of instruction and lectures are given to all medical officers charged with the care of flying personnel. The book, indeed, gives the impression of having been compiled during the stress of war and to take little notice of contemporary work on medical aviation. No doubt the authors have themselves moved forward since then in their methods and practice, and we should like to see any set of forms now in use for the examination of pilots in flying, together with proper statistical tables of the results.

Dealing with the physical examination of candidates, the authors advocate the anthropometric factor of Bouchard and do not mention the work of Professor Georges Dreyer. They follow the physical measurement of a candidate with an inquiry into his family history, and apparently recommend that if this is unsatisfactory on account of epilepsy, madness, paralysis, or tabes he should be rejected. It seems a waste of time to go to the trouble of taking physical measurements if the applicant is to be rejected on other grounds. The methods of examination of the heart are not described, and reference is made to instruments unfamiliar to the practitioner in this country. Here some explanatory notes with diagrams and instructions would have been useful. The all-too-short description of a special apparatus for measuring equilibrium is of interest. With these provisos the book is one that can be recommended to English readers for its conspectus of air medicine in France.

ADVANCED LESSONS IN PRACTICAL PHYSIOLOGY.

For Students of Medicine. By RUSSELL BURTON-OPITZ, S.M., M.D., Ph.D., Associate Professor of Physiology, Columbia University. Illustrated. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 238. 18*s.*

THIS excellent guide to experimental physiology is essentially on the plan of teaching practised in English schools of medicine. It is made up of 50 lessons, each for a practical class lasting three hours; 9 lessons are allotted to muscle and nerve, 3 to blood, 13 to heart and circulation, 6 to respiration, 4 to nervous system, 7 to the sense organs, 5 to digestion and absorption, and 3 to excretion—a very judicious and well-balanced distribution. The subject is presented in a practical manner—practical in the sense that many of the exercises lead up directly to the future clinical work of the student. Obviously in American schools of medicine the conditions under which a student is allowed to perform experiments—blood pressure, sections of nerves, fistulæ, tracheotomy, ligature of vessels, &c., under proper anæsthetic safeguards—are far different from those allowed in this country. In the higher grade medical schools in the United States about 300 hours are allotted to physiology—exclusive of physiologic chemistry and clinical physiology or experimental medicine—about 180 hours being [illegible] to practical work and 120 to lectures and con[illegible] Each student must devote 10 hours per week to physiology in an academic session of 30 weeks. At the end of the book a list is appended of over 30 demonstrations given in connexion with the preceding lessons. These include demonstrations on Pflüger's law, electrical phenomena of muscle and nerve, galvanometers, electro-cardiography, polygraph, decerebrate pigeon and cat, lesions of cerebellum, semicircular canals, removal of thyroid, parathyroid, and suprarenal glands, &c. The text is illustrated with 213 figures, some in colour. Perhaps Zöllner, the astronomer of Leipzig, would have preferred his name printed with umlaut instead of as on pp. 204 and 238. Any student who works carefully on the lines here laid down will find that he has acquired an admirable training for his future clinical work, and indeed for other subsequent subjects of his medical career. This is a comprehensive, judicious, well-selected and admirably practical course on experimental physiology—a meet companion to the author's text-book (THE LANCET, July 24th, 1920, p. 190).

THE PSYCHOLOGY OF PHANTASY.

Collected Papers. By CONSTANCE E. LONG. London: Baillière, Tindall, and Cox. 1920. Pp. 216. 10*s.* 6*d.*

THIS book consists of a number of papers written by Dr. Constance Long during the past four years, some of which have already appeared in various journals. Dr. Long is one of the leading exponents in this country of that "Analytical Psychology" which is associated with the name of Dr. C. G. Jung, of Zurich, and in these papers she expounds in an elementary and popular way some of the main tenets of the school to which she adheres. Here, as in the school of Freud, great importance is ascribed to phantasy and dream, but each school puts its own interpretation on the real significance of these products of unconscious functioning. Dr. Long lays stress on the compensatory function of the unconscious and of the prospective or teleological character of the unconscious thoughts and feelings which emerge in dreams and phantasies. The balancing or compensatory function of the unconscious implies that what is missing in the conscious will be found in the unconscious, and that for the purpose of adaptation to life both the conscious and the unconscious attitude towards any given situation should be taken into account. Indeed, it would seem that Jung and his followers are coming to lay more and more stress on the importance of the guidance in the actual conduct of life which can be obtained from dreams and other products of the unconscious. Dr. Long says that Jung, like Freud, attributes neurosis to repression, though he does not base its whole ætiology on sexual repression, but on a one-sided development of the various psychological functions of thinking, feeling, sensation, and intuition. Whatever is repressed or under-expressed links itself up with unconscious elements, and from the psychic tension produced between what is conscious and what is unconscious, the phantasies arise, representing in symbolic form what is missing from conscious consideration. But, according to this view, what is missing from consciousness seems to be missing mainly because it is "neglected." Neglect, however, is a very different thing from repression. The predominating psychological function is said to be over-developed, the other functions being "relatively repressed," but it is hard to find any justification for using the term "repression" to account for the presence in the unconscious of the relatively undeveloped or undifferentiated function.

In a book of this kind, consisting of a number of separate papers, it is inevitable that there should be a considerable amount of repetition, but for those to whom the subject is new this will be no drawback. The topics dealt with are by no means easy of comprehension, and there is much to be said about them that could not readily find a place in these papers. Those readers who accept the doctrines of Freud will find little in this book to coincide with their beliefs, but for the followers of Jung it will prove a useful and interesting compendium of the views to which they subscribe.

GEORGE MILLER STERNBERG.

A Biography. By his Wife, MARTHA L. STERNBERG. Chicago: American Medical Association. 1920. Pp. 331. $5.

George Miller Sternberg was born in 1838 and died in 1915. He received his medical education at Buffalo and at the College of Physicians and Surgeons in New York City, which body gave him the degree of M.D. in 1860. He proceeded to Elizabeth City, N.J., directly afterwards, where he practised until the outbreak of the Civil War, when he was appointed assistant surgeon, U.S. Army, on May 28th, 1861. During the war he saw a good deal of service, and, amongst other experiences, was taken prisoner at the battle of Bull Run, but managed to escape. After the war he served in various places, mainly frontier posts. He had much experience of Indian fighting, and in 1875 suffered from a severe attack of yellow fever, from which, however, he recovered. He was granted six months' sick-leave and went to Europe to recruit, returning to the States in 1876. He served through the Nez Perces campaign of 1877, and in 1879 was made a member of the first Havana Yellow Fever Commission, which was the outcome of the widespread mortality from that disease during 1878. Much good work was done by the Commission, but the specific cause of the disease remained a mystery.

For the next ten years Sternberg did the bacteriological work for which he is so justly well-known, and discovered in February, 1881, the pneumococcus, which had, however, been already described by Pasteur in January of the same year. He had never lost his interest in yellow fever, and in 1887 he took up the subject again on behalf of the Government Commission which had been appointed. In 1890 he published his conclusions, which were negative. In 1900 Sternberg, who had been appointed Surgeon-General of the army in 1893, instituted the Yellow Fever Board, which in turn appointed a Commission, with Major Walter Reed as President. This Commission went to Havana in 1900, where Reed and his companions established the fact that yellow fever was transmitted by the bite of a mosquito, even though the actual causative organism remained unidentified. In 1902 Sternberg retired from the army and was given the chair of Preventive Medicine in George Washington University, and from this date until the time of his death he devoted himself to the anti-tuberculosis campaign and matters of public health.

Mrs. Sternberg has written an interesting account of a long and busy life. Sternberg's researches are one more instance of the fact, so well known in scientific work, of how apparently unsuccessful toil leads to great results. It was his patient research in eliminating the causes to which yellow fever is *not* due, which paved the way for the immortal work of Reed, Carrol, and Lazear, and enabled Gorgas to carry to a successful conclusion the Panama Canal.

JOURNALS.

Journal of Neurology and Psychopathology. Vol. I., Nos. 2 and 3.—The second number of this new journal maintains the promise of its first. The chief article is one by Dr. R. M. Stewart, of Prestwich, on the Histopathology of Carbon Monoxide Poisoning, the case being that of a man who died from the effects of gas-poisoning on the twenty-fourth day of his illness. Histological examination revealed the presence of an intense and universal myelin degeneration, bilateral softening in the basal ganglia, and a widespread cortical softening strictly confined in a curious way to the deeper layers of the grey matter. Dr. Stewart considers that this peculiar selective action of what must certainly have been a diffuse intoxication is to be explained by certain anatomical peculiarities of the blood-vessels supplying the central nervous system. It seems clear that an anoxæmia alone could not have produced the peculiar zones of softening and that carbon monoxide must have a specific action of its own on the parenchymatous elements of the nervous system.—Dr. William Brown, of London, contributes a brief paper on Some Factors in Psychotherapy, emphasising the importance of what he calls psychocatharsis, a process by which suppressed emotions are worked off, while at the same time reassociation of forgotten incidents takes place in the mind. He also describes the working of another therapeutic process called by him autognosis, in which the patient is led backwards in memory and encouraged to discuss emotional memories of the past, especially those where he failed to adapt himself adequately to his physical and social environment.—A clinical paper on the Acute Confusional States in the Psychoneuroses is contributed by Dr. W. Johnson, of Liverpool, based on his examination of some thousands of military cases admitted to an army centre for psychoneurosis. About 10 per cent. showed definite evidence of confusion. Three fairly distinct types appeared—(1) simple type with short confusional period of not more, perhaps, than of 24 hours; (2) severe type of pronounced but temporary state of confusion; (3) type associated with definite mental disorder.—The Nature of Insomnia in Cases of Psychoneurosis is discussed by Dr. R. G. Gordon, of Bath, who comes to the conclusion that the insomnia is the result of the patient's giving his attention to keeping some unpleasant or insupportable idea out of his mind, and trying to cut it off from all other associations. This effort of attention is the first step towards the formation of a barrier which will repress the complex. Since, however, in order to achieve normal sleep all effort of attention must be relaxed, the patient finds himself in a sort of impasse, for if attention be relaxed, then the complex finds expression in consciousness and disturbs the monotony necessary for sleep; on the other hand, to avoid this relaxation of attention he becomes more alert than ever, and the more he tries to sleep the wider awake he seems to become.—Dr. M. A. Blandy, of London, describes in a brief clinical note a typical case of Torsion-spasm or Torsion-dystonia, apparently the first that has been recorded in England, and her article is illustrated with excellent clinical photographs.—Dr. Aldren Turner, of London, publishes a critical review on Modern Opinions in Regard to Epilepsy.

In the November issue the first article is from the pen of Professor C. Lloyd Morgan, of Bristol, and is concerned with the question of Psychology in the Medical Curriculum. The article is written in that delightful literary style of which Professor Lloyd Morgan is a master, and constitutes a cogent plea for the instruction of all medical students in psychology. Man is not only a complex physiological system, but an equally complex psychical system, and the time has come to consider whether the psychologist should not have a status on the staff of a medical school analogous to that of the physiologist.—A clinical symposium on Epidemic Encephalitis, for which Sir Thomas Horder supplies a brief introduction, is contributed by a number of writers from Bristol and its neighbourhood, where in the course of the summer and autumn a definite local epidemic has been raging. The clinical descriptions of the various types of the disease then encountered constitute a useful contribution to a subject of great practical importance.—The Importance of Education in the Prevention of the Neuroses receives consideration in a paper by Dr. J. Ernest Nicole, of Manchester. Psychologists and others are coming to the conclusion that the normal and abnormal developments of child mentality exercise their influence on adult character, and that there is a great need for an individual and rational education which will help to close the wrong paths and open up the right ones that are essential to human progress and development.—A remarkable series of cases of Familial Tabes Dorsalis has been under the care of Dr. J. Le Fleming Burrow, of Leeds, who supplies the details in a short article. Briefly, of six surviving members in a family of eight born of healthy parents, four acquired undoubted syphilis from absolutely different sources, yet with a resulting tabes dorsalis in all. The conclusion is justified that tabes cannot be attributed to a special strain of spirochæte introduced at the time of the initial infection, but is much more likely to be due to the spirochæte acting upon tissues specially sensitised either by natural familial peculiarity or by certain methods of treatment.—Dr. Henry Devine, of Portsmouth, writes a critical review on the Neuropathic Individual as a Social Unit, with special reference to the recent illuminating work by Professor Pierre Janet in this connexion.

The Journal of Physiology. Edited by J. N. LANGLEY, Sc.D., LL.D., F.R.S. Cambridge University Press. 1920. Vol. LIV., No. 4. Pp. 203–318. Price 9*s*.—The Influence of Venous Pressure upon the Heart-rate, by K. Sassa and H. Miyazaki. The authors confirm Bainbridge's results as to reflex effects on vagus and accelerator tone. They find that the greater the vagus tone, the more effective is the rise of venous pressure upon the acceleration of the heart in different species of animals or different individuals of the same animal. In frogs and rabbits where the vagus tone does not normally exist, no appreciable accelerator effect was found, the sympathetic nerves alone being not sufficient to produce this effect.—On the Correlation of the Rate of Heart-beat, Breathing, Bodily Movement, and Sensory Stimuli, by Water M. Coleman.—Studies on Muscular Contraction. I., The Influence of Temperature on the Mechanical Performance of Skeletal and Heart Muscle, by Yasukazu Doi.—On the Existence of

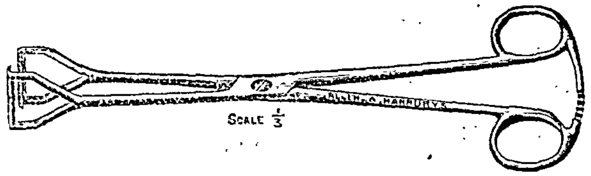
Antidromic Fibres in the Frog and their Influence on the Capillaries, by Yasukazu Doi.—On the Permeability of Epithelial Layer of the Bladder to Water and Salt, by Rinnosuke Shoji.—Cardiac Tetanus, by W. Burridge. Under certain conditions the superposition of contractions and a condition approximating to the tetanus of skeletal muscle is possible in the heart—e.g., poisoning of heart with muscarine or chloral hydrate. The author's experiments on the perfused frog's heart were performed on hearts subjected only to alterations in the proportions of their normal environment. They indicate that the greater richness of cardiac muscle in phosphates as compared with skeletal muscle is an important factor in determining its mode of behaviour. The author describes the chemical constitution of the perfused fluids which enabled him to obtain a preparation which can be fatigued, thrown into tetanus, and shows von Kries's phenomenon, such as are manifested in skeletal muscle. His experiments indicate that differing capacities to adsorb different elements of a common environment may be an important factor in determining differences of muscular behaviour.—Variations in the Resistance of Protozoon Organisms to Toxic Agents, by R. A. Peters. The author experimented with a culture of the ciliated protozoon colpidium, using a heat-standardised solution of $HgCl_2$ as the toxic agent. The animals die in such a way that there is a straight-line relationship between the time and the logarithm of the percentage of survivors for a large part of the death process. The apparent logarithm law can be interpreted in terms of the variation in the resistance of individuals of the protozoon culture to the toxic agent.—The Action of Certain Serum Constituents upon the Heart and Plain Muscle, by A. J. Clark. Various preparations and derivatives from sheep's serum were used on isolated tissues of the frog and mammal. The action of the serum is the sum of the serum proteins and of the alcohol-soluble constituents, but these two sets of substances have totally distinct actions. The serum proteins produce strong vaso-constriction and have little action upon other tissues, while the alcohol substances produce slight vaso-dilatation, a great augmented effect on the frog's heart, a moderate augmented effect upon the frog's stomach and the mammalian gut and uterus, but no effect upon the mammalian auricle. The mode of preparing the serum derivatives probably removed such substances as adrenalin and histamine that might be present in the serum. The action of the alcoholic extract of serum and of lecithin in stimulating plain muscle indicates that an alcoholic extract of any tissue is likely to cause stimulation of plain muscle and that this general action must be distinguished from the specific action of special glands such as pituitary extract.—The Effect of Alterations of Temperature upon the Functions of the Isolated Heart. By A. J. Clark.—Physical Exertion, Fitness, and Breathing, by Henry Briggs. Experiments were made to determine the oxygen consumption of persons engaged in different kinds of physical work. The methods and apparatus used are described, including ergometer tests and the results of walking and climbing experiments. Experiments were made on men climbing the main incline in a limestone mine in Midlothian, while breathing normal air and while breathing oxygen. Physical work is easier to unfit men when oxygenated air is breathed than when normal air is breathed, but no such difference is to be observed in fit men. When exertion of steadily increasing magnitude is undertaken the expired CO_2 percentage first rises and then falls. The load at which that percentage is a maximum the author calls the "crest-load," which also demarcates between normal loads and overloads, but the demarcation line is not constant. On an overload even the fittest man derives benefit from breathing "enriched air." The benefit of breathing enriched air when doing physical work is limited to air containing about 60 per cent. oxygen. Enrichment above that proportion has no effect during exertion except on unfit persons. Tables showing the oxygen consumption when walking, running, climbing, or doing ergometer work are given.—Other papers deal with Nitrite Methæmoglobin and Related Pigments, by H. Hartridge. The author gives evidence in favour of this substance being a definite chemical compound. The use of thermionic valves—a well-known piece of mechanism used with wireless apparatus and long-distance telephony—in combination with the string galvanometer, as applied to obtaining an electro-cardiogram, is described by I. de Burgh Daly and K. E. Shellshear. H. Hartridge makes an interesting suggestion as to "the ear as morphologically an apparatus for perceiving depth below sea-level," which was fully referred to in an annotation in THE LANCET last week.

THE Medical Branch of the Board of Education has been transferred from Cleveland House, St. James's-square, London, S.W., to Bridgewater House, Cleveland-row, London, S.W.1. (Telephone: Gerrard 3410.)

New Inventions.

IMPROVED DUVAL'S FORCEPS.

WHEN using Duval's special lung forceps in chest cases during the war I was impressed with their extremely sensitive and at the same time assured non-slipping grip, and came to employ them largely in abdominal surgery, where their tenacious but delicate hold proved invaluable, notably for holding or retracting the uterus, appendages, cysts, small tumours, and even gut when applied over gauze. The original model has a triangular head, of which the angles are too prominent and the bite wider than necessary. I have therefore modified it (see illustration) by removing the sharp angles of the jaws and increasing the length of the instrument, thus making it more suitable for deep abdominal work. The bowed end lock prevents sutures getting caught up between the finger rings as in the ordinary pattern of forceps.

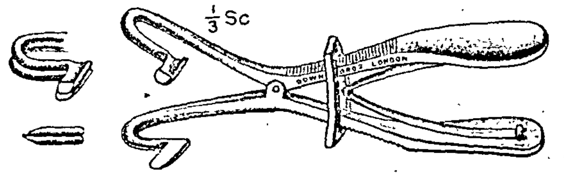


Messrs. Allen and Hanburys, of 48, Wigmore-street, London, W., are the makers of the instrument.

BRYDEN GLENDINING, M.S. Durh., F.R.C.S. Eng.
Aspley Guise, Beds.

AN IMPROVED MOUTH-GAG.

THE frequent difficulty of inserting the tooth-plates between the teeth in an emergency as well as the liability of the gag to slip forward and outward when they open the jaws are overcome entirely by the mouth-gag illustrated. Its chief features are as follows: There are projections extending inwards from the tooth-plates; these are set at a knife-edge and in cases where patients are anæsthetised with their jaws closed the gag can be inserted quickly and easily between the teeth and the mouth opened. The advantages of this non-cutting knife-edge must be obvious to all anæsthetists; and in cases for dental extractions, particularly where the prop, which is often used, fails or falls out, it is specially useful. With this gag the prop can be dispensed with for dental extractions. There are ridges, or lips, at the posterior and inner edges of the tooth-plates, and these effectually prevent the gag slipping forwards and outwards when the mouth is forced open. There are no ridges on the anterior and outer edges, as the gag when opened does not tend to slip backwards or inwards. The angles and length of the gag are so arranged as to give the greatest leverage possible combined with strength and lightness. The handle is broad and concave, and facilitates the opening of the gag, as it provides a large broad surface for the hand.



There are fine serrations on the ratchet and these allow the gag to be fixed open in any desired position. It is unnecessary and undesirable to use rubber to cover the tooth-plates; the spring is detachable and easily cleaned.

The instrument has been made for me by Messrs. Down Bros., Ltd, St. Thomas's-street, London, S.E.

THE LANCET.

LONDON: SATURDAY, JANUARY 8, 1921.

Medicine and Industry.

THE annual report of the Medical Research Council for 1919–20, which has just appeared,[1] points out that the problems of industrial medicine are not easily separable from those of public health in general; the overwhelming majority of the people are engaged in industry, and the greater part of prevalent disease is connected either in its origin or its extent with industrial occupations and the conditions of life which have been imposed during industrial development. When the Medical Research Committee was reconstituted as the Medical Research Council, in the middle of the year's work under review, it entered thereby into relationship with the needs of other State departments without loss of direct touch with the Ministry of Health; it came to form a constitutional nexus of a novel kind between the scientific forces of the country and the State. It would be hardly fair yet to look for results from the drawing together of this fine mesh; research is necessarily limited by the supply of well-trained men of ability available to do it. But fortunately in the field of industrial medicine it has not been hard to find eager minds, and the Industrial Fatigue Research Board, as to one half of which the Medical Research Council is responsible, has made investigations in the iron and steel trade, the cotton trade, the boot and shoe trade, the silk trade, and laundry work—the task of the Board being to combine these investigations into a concerted scheme. Great issues of health and happiness to the human race are inherent in this task, which should make an economic return altogether incommensurable with its small cost.

The outlook for industrial medicine is full of promise. Although medical service in the factories and mines of this country, when compared with the United States, is developing somewhat slowly—due possibly to the long overdue remodelling of the office of certifying factory surgeon—nevertheless important steps are being taken. The labour world, without waiting for legislation, is busy profoundly modifying hours of work: the 48-hour week has come to stop; work in factories before breakfast has almost entirely ceased, with a suddenness no one could have foretold a few months ago—soon it will become merely a subject of antiquarian interest. An Act has been placed on the statute-book permitting machinery tended by women and young persons to run for 16 hours daily, from 6 A.M. to 10 P.M., so long as no protected person is employed for more than eight hours a day; the effect of this Act upon the elasticity of employment and of production may be far-reaching. Full advantage is being taken of the powers conferred by Sec. 7, Police, Factories, &c. (Miscellaneous), Act, 1916, to make orders concerned with the provision of welfare accommodation in many industries; these orders relate to drinking water, first-aid stations, seats, cloakrooms, meal rooms, and rest rooms; in practice they simultaneously call into existence welfare supervision, and cannot fail to exert a widespread influence upon the health of industrial workers. The inspectorial staff of the Factory Department are being reorganised to deal with their new responsibilities, and the medical strength is being increased, notably by the appointment of a woman doctor. These officers have even further duties to anticipate, since a new Act consolidating legislation passed since 1901, when the last main Act was passed, may be shortly expected. Further legislation restricting the use of lead in paints may ere long be introduced in order to deal a last blow at plumbism, which would thenceforth become a medical curiosity.

Meanwhile, the Industrial Fatigue Research Board is settling down to its work, and, as the results of careful investigation, is publishing reports, to which attention has from time to time been directed in these columns, setting forth knowledge of practical value to industry and gradually revealing the laws which guide the working of the human machine. Employers reading these reports must be struck with the way in which the same ends serve the interests of productivity and of health. A new science, the science of activity and health, is here rapidly developing. The Mines Regulations Acts have received fresh inspiration from transference to the Ministry of Mines under a special department devoted to safety and health; while an expert committee of the Medical Research Council is giving close attention to that distressing and increasingly prevalent disease, miners' nystagmus. The first scheme under the Workmen's Compensation (Silicosis) Act, 1918, has been established; it only applies to a small but important industry, the refractories industry, which includes ganister mining; but it may well be the forerunner of more extended schemes dealing with the grinding of metals on sandstone wheels, the potteries, stonemasonry, and other industries with exposure to inhalation of silica dust. Kindred work going on in South Africa on the gold-fields cannot fail, as it throws light on the ætiology and prevention of silicosis, to influence in this country schemes drawn up under this Act. All in all, medicine and industry are running well in harness.

◆

The Vital Properties of Milk.

FROM time to time we have drawn attention in our columns to irreconcilable statements concerning the loss of vital and nutritive properties sustained by milk on sterilisation or on cooking. In the light of recent bio-chemical advances in relation to the dependence of growth and nutrition upon certain accessory food-factors, we take some credit to ourselves for having anticipated, as far back as 1901, the views which are to-day held in scientific circles with respect to the changes brought about in milk by heat. Although there is good evidence to show that the excessive or repeated cooking of milk does, in some way, render it unfit as an exclusive food for infants, there is no reason for suggesting that such milk sustains any loss of nutritive value having regard to its main constituents. Those who claim that milk is less nutritious when boiled than in the raw state should make it clear to themselves as well as to others what they exactly mean by loss of nutritive value. The caloric value of boiled milk is identical with that of raw milk, but all the same boiled milk, or perhaps more accurately speaking overcooked milk, will not serve as an exclusive food for infants or, indeed, for adult individuals, for the reason that it contains in deficient amount certain accessory factors which are essential for growth and adequate nutrition. The name vitamines, which has been given to these intangible substances, cloaks our ignorance rather than reveals the truth.

---

[1] H.M. Stationery Office. Cmd. 1088. Price 9d.

It is claimed that in raw milk there are at least three varieties of vitamines, one of which—viz., the anti-scorbutic—is destroyed or impaired in quality by exposure to heat. It was suggested by Professor Gowland Hopkins at the last meeting of the British Medical Association that it was not so much heat that destroyed this vitamine as oxidation processes to which a rise of temperature conduced. This view is supported by a vast amount of clinical evidence which goes to show that infants can grow and develop perfectly satisfactorily on dried milks which have been submitted to considerable degrees of heat without any supplementary addition of the anti-scorbutic vitamine in the form of fruit juice or other substitute. Authorities are, however, at the present time fully agreed that, since there is a risk of loss of activity in the properties of the anti-scorbutic vitamine on exposure to heat, or by prolonged preservation, it is a wise precaution to provide a supplementary supply of this accessory food factor whenever cooked foods constitute the exclusive dietary of growing children. The wider deduction that the nutritive value of boiled milk when used as a component element in a mixed dietary is inferior to that of unboiled milk is quite unjustifiable and possibly dangerous, for there is ample evidence to prove that unboiled milk can be a serious source of danger as a medium for the conveyance of many infective diseases in addition to tuberculosis itself. Even if we admit that immunity to tuberculosis, and possibly other diseases, may be acquired by the repeated oral ingestion of such small doses of the living bacilli as raw milk commonly contains, the occasional and beneficent result cannot compensate for the risk of a lethal dose of the same poisons contained in more seriously infected milk. If prophylactic inoculation against specific diseases is to be secured by the inoculation of the living germ, surely it is wiser to secure the desired end by means of the accurate and measured doses of the bacteriologist than by the haphazard and possibly dangerous method of employing the accidental impurities of milk.

The Subcommittee on Milk appointed by the Standing Committee on Trusts under the Profiteering Act have issued a Report this week, in which they come to the satisfactory conclusion that the large combinations of distribution have dealt fairly with the public, and in which they also make some interesting comments on the milk-supply of the country. Perfectly clean raw milk, in a bacterial sense, is an impossibility, but milk with a very low bacterial count is a practical proposition. In a circular issued to the local authorities by the Ministry of Health last autumn attention was called to the regulations in regard to the sale of graded milk, but little advantage appears to have been taken of the official arrangements. We think it very desirable that producers and distributors should be encouraged to undertake the supply of high-grade milk in accordance with the prescribed conditions. The designations of graded milk are: (1) Grade A Milk, and (2) Grade A (Certified) Milk. former is defined as milk produced under lly clean and hygienic conditions from a herd m tuberculosis, and it should be a matter of common kowledge that such milk is fit for human consumption without being heated. Grade A (Certified) Milk, also obtained from a herd free from tuberculosis, must be bottled in accordance with certain rules and show a satisfactory result on bacteriological examination. This is as near as we can get to a perfectly clean raw milk, and it can only be put upon the market at an enhanced price and treated as a medical diet. The public are advised to insist upon its supply to them should their doctors consider it essential, when retailers and combinations will allow them to have their rightful way. On the other hand, pasteurised, sterilised, and bacteria-free dried milk can be supplied to the public, not only without raising the cost of production, but actually with a considerable saving. In a recent contribution by Mr. R. Stenhouse Williams, of the Research Institute in Dairying at Reading, he shows that the loss of milk in the London area alone from souring represents something like a million gallons a year. Although the greater part of this loss could be obviated by increased care and cleanliness in the production, the application of heat in the form of pasteurisation or sterilisation would probably effect the same object at a smaller cost. For the above and other reasons it is important that irresponsible statements with regard to the impaired nutritive qualities of cooked milk should not gain a wider currency than is at present the case. There is, however, a wide field for research still open in connexion with the nature of those illusive accessory food factors which are essential for satisfactory nutrition, which are known to exist in raw milk, and which, if cooked milk is employed, can be supplied from other safe sources.

◆

The Insurance Medical Records.

The Insurance Medical Records, both the way in which they are to be collected and the policy which has led to their existence, are being criticised in certain quarters of the public press, and although the controversy has not met with much reflection among the vast body of persons immediately concerned, sufficient distrust has probably been engendered to prejudice the work of the Ministry of Health in this direction. All who have been made to feel uncomfortable should purchase for themselves through any bookseller, or directly from H.M. Stationery Office, at the price of *3d.*, the Report [Cmd. 836] of the Inter-Departmental Committee which was published last summer. This Committee was appointed to decide upon the form of medical record to be employed under the terms of service for Insurance practitioners in the New Medical Benefit Regulations, 1920, and its conclusions were commented upon favourably at the time, not only in The Lancet[1] but in the general press. A full abstract of the Report was published in the *British Medical Journal*, when the serious faults now alleged against the document went unremarked. Correspondence ensued predicting irritation at the waste of time involved in the procedure laid down, and at the Conference of Local Medical and Panel Committees, held under the ægis of the British Medical Association in October last, there was opposition on this and other grounds, but the serious crime of incitement to the violation of medical confidence was not suggested.

---

[1] The Lancet, July 31st, 1920, p. 254.

The regulations under the Insurance Acts *require* that records should be kept by all practitioners accepting panel service of the treatment of their patients; and the fact that during the war this work fell into abeyance cannot be used as any argument for depriving the nation of the value that may be derived from the maintenance in respect of the individual patients of a continuous medical history. Moreover, such records form evidence that those who have charge of a vast proportion of the health of the country are carrying on their duties in an orderly manner, and especially in a manner which shall make the study of disease a coherent thing and not dependent upon changes of individual practitioners. The aim of the Ministry of Health was from its earliest days to bring preventive medicine into its proper place as the ideal of every doctor, and, through the doctor, of the whole country. No pains, it was decided, ought to be spared in ensuring that the treatment of the diseases which are with us should be prompt and adequate; but, over and above, it was considered necessary—and this with universal approval—to take all possible precautions against the spread of these diseases, using every weapon that came to hand against early manifestations. Prevention and early detection are alike simplified by the possession of continuous records. In making the records required by the National Insurance Acts the rival claims, arising out of the need for statistical information and of the ability of the hard-worked practitioner to supply it, must be adjusted. All useless copying from card to card must be avoided, and only such clinical information as will be useful to the practitioner or his successors in charge should be included. This is the scope of the records required by the Ministry of Health. It is true that such records will be far less valuable to science than more elaborate notes properly collated might be, but neither the time nor the reward of the general practitioner allows for anything more.

All must agree that the objects in view, when it was decided that these records should be kept, were sound, though the machinery may be open to criticism. Now, however, and very late in the day, it is suggested that to keep these records is in itself a violation of one of the primary rules of medical ethics—namely, that the doctor should never disclose, save with the patient's permission, the medical confidences he has received. We have every sympathy with those who, in all times and in all places, fight for this great privilege of our profession, but we find here that the sentiment is being strained. The privacy of the records is well guarded and their contents are so limited that any hurtful leakage can hardly occur. It has been objected by different members of the medical profession that the records are too scanty to be valuable, and also that the writing out of forms ought to be left to clerks. We must point out that the two objections are mutually destructive. To take the work of keeping the records from the doctor to give them to clerks certainly spares the doctor from doing non-medical work and would allow the records to be much fuller, but the procedure would blow sky-high any defences against ethical indiscretion.

INDEX TO "THE LANCET," VOL. II., 1920.

THE Index and Title-page to Vol. II., 1920, which was completed with the issue of Dec. 25th, will shortly be published in THE LANCET.

Annotations.

"Ne quid nimis."

NEW YEAR HONOURS.

THE honour of knighthood has been conferred upon four medical men in this country: Mr. Charles Ryall, senior surgeon to the Cancer Hospital and to the Bolingbroke Hospital; Dr. William Hodgson, sometime mayor of Crewe and well known for his services to scientific education in Cheshire; Dr. Dawson Williams, editor of the *British Medical Journal*; and Dr. Squire Sprigge, editor of *The Lancet*. The chairman of the Irish Public Health Council, Dr. E. Coey Bigger, also receives a knighthood, and Dr. Alexander J. Hood, of Sydney. Among naval and military honours Major-General Robert Porter, M.B., becomes C.B. (civil division); four lieutenant-colonels in the Indian Medical Service receive the C.I.E.—namely, David M. Davidson, Frederick O'Kincaly, William Frederick Harvey, and John L. Van Geyzel. Dr. Frederick S. Hewett, surgeon-apothecary to the King and to Queen Alexandra, has been appointed K.C.V.O. To all our colleagues we tender our hearty congratulations.

A FUNCTION OF THE GREAT OMENTUM.

THE question of intraperitoneal absorption of microscopic particles, alive or dead, is one of considerable clinical importance, and the respective parts played by the diaphragm and great omentum have not infrequently been the subject of experimental and pathological investigation. Several years ago the younger Heger, of Brussels, showed that the omentum was a vigorous absorber of fine inorganic particles—of China ink—in fact, a kind of "sweeper" of the peritoneal cavity. Finely granular particulate substances, such as carmine, China ink, starch grains, lycopodium powder, are known for the most part to pass into the lymphatics of the diaphragm, whence they reach, via the lymph stream, the liver, lungs, and spleen, where they are stored up. The question remains, however, how they reach the lymphatics, directly or by phagocytic leucocytes. The classical experiment of Ludwig showed that through the central tendon of the diaphragm and its stomata coloured fluids—e.g., soluble Brücke's blue—rapidly passed into the lymphatics, even in the dead rabbit, when the movements of the diaphragm were imitated by artificial respirations. This was proved by a really beautiful display of the blue injected lymphatics. Granular particles are absorbed by the same surface, although this obviously must depend on the size of the stomata. By coating the under surface of the central tendon with collodion in animals, Clairmont, Haberer, and Peiser showed that the absorption of fluids from the peritoneal cavity was considerably diminished. E. Seifert, of Würzburg,[1] adds considerably to our knowledge of the function of the great omentum and the channels and means of absorption of finely divided particles present in or introduced into the peritoneal cavity. The experiments were made on guinea-pigs, and by way of identifying the specific forms of leucocytes that might be concerned in the process, the method of vital colouration or staining by means of a 1 per cent. solution of isamin-blue was used, the fluid being injected (6–10 times) at certain intervals under the abdominal wall. The omentum was fixed in formalin, stained, and studied, when it was found that the migratory leucocytes, the fibroblasts of the connective tissue, and the cells covering the serous membrane were coloured in the chief degree, and very faintly the epithelium of the convoluted tubes of the kidney. The groups of cells—visible to the unaided eye in the omentum, and long ago described by Ranvier as "*tâches laiteuses*" (milk spots)—were coloured blue, and the leucocytes of which they principally consist had blue-coloured granules in their protoplasm. With a view to a further study of foreign granular particles in relation to the omentum, animals previously injected with isamin-blue had 3 c.cm. of a 10 per cent. emulsion of China ink in warm normal saline injected into the abdominal cavity, and were then killed at varying intervals. A certain proportion of the black particles rapidly disappeared from the cavity via the lymphatic vessels of the diaphragm, and were carried by the blood stream and stored in the star-shaped Kupfer cells of the liver, and in the lungs and spleen. The remaining particles were "phagocytised" by the microphages, and from the second day onwards there was a great increase of the cells of the milk spots, the spots themselves becoming larger and new ones being developed. The wandering cells laden with ink particles returned to the omentum and formed "spots." These cells died slowly, the spots themselves became surrounded by concentric layers of fine connective tissue, the capillaries degenerated, and the spots passed into a permanently passive state. There are no lymphatics present in the great omentum.

---

[1] Brun's Beiträge z. klin. Chirurgie, vol. cxix., 1920.

After the injection of a virulent emulsion of bacteria, phenomena similar to those of injection of China ink are observed. Some of the tubercle bacilli pass via the lymphatics of the central tendon of the diaphragm to the retrosternal gland and there excite tuberculous inflammation. The bacteria also pass to the liver, spleen, and lungs, where again specific tuberculous change is set up. The remaining bacilli are taken up by the leucocytes originating in the omentum, which return laden with bacilli to the omentum, causing excessive growth of milk spots in which the omental tubercles develop. In the case of China ink particles a state of repose or subsidence of action is set up in the milk spots, but in the tubercle invasion the phagocytes composing the spots are not able to overcome the infective pathological attack. The phagocytes themselves disintegrate, as shown by their inability to undergo vital staining, and there results an aggregation of tubercles. In spite of its marked absorptive and protective functions the omentum is not able to ward off the invasion of infective processes from the other surfaces of the peritoneal cavity.

TUBERCULOSIS OF THE STOMACH.

ACCORDING to Dr. Wilhelm Baetzner,[1] assistant at Professor Bier's surgical clinic in Berlin, who records an illustrative case, tuberculosis of the stomach is very rarely found at autopsy. The statistics of the Kiel Pathological Institute show that among 2000 cases of tuberculosis there were only eight examples of the kind, and Eisenhardt, among 6000 cases of tuberculosis, which included 600 of intestinal involvement, found only one case of tuberculosis of the stomach. Clinical cases are naturally rarer still, according to Albu only about two dozen genuine examples being on record. Tuberculosis of the stomach is usually secondary to pulmonary or miliary tuberculosis. Infection may take place by the blood and lymph stream, but is usually produced directly by the swallowing of infected sputum. The rarity of gastric infection is due to the physiological action of the gastric juice and the active movements of the stomach and also to the anatomical structure of the organ with its scarcity of follicles. The lesion usually found is an ulcer, which is situated most frequently at the pylorus and is liable to all the complications of ordinary gastric ulcer such as hæmorrhage, perforation, and fistula. The symptoms are the same as those present in ordinary gastric ulcer or carcinoma—viz., dyspepsia, motor and chemical disturbances, and stenosis—when the pylorus is affected. Dr. Baetzner's patient was a woman, aged 38, who sought advice for a feeling of hunger and severe pain half an hour after food. Nothing could be detected on palpation. Gastric analysis showed an absence of free hydrochloric acid and the presence of lactic acid, and the X ray examination indicated an ulcer on the greater curvature. On operation, at which Dr. Baetzner performed transverse resection, the ulcer w[illegible]ed to involve the mucous membrane only. Its floor was studded with nodules and the stomach showed a well-marked inflammatory infiltration. On microscopical examination typical miliary nodules were found in the mucosa and submucosa, but no bacilli were seen. The patient remained free from symptoms for three months and then had a recurrence of nausea and vomiting, with loss of weight. A second laparotomy was performed and posterior gastroenterostomy carried out. Recovery was delayed owing to the development of active disease in the lung. At the time of publication there was distinct improvement, but the outlook was doubtful owing to the possibility of a recurrence of the gastric process.

SPLENIC LEUKÆMIA IN PREGNANCY.

AT a recent meeting of the American Association of Obstetricians, Gynæcologists, and Abdominal Surgeons, Dr. George W. Kosmak,[1] of New York, read a paper on splenic leukæmia in pregnancy, of which he had collected 12 examples, including two cases of his own. The ages of the patients ranged from 24 to 40, the majority being between 32 and 36. All but one were multiparæ. A possible hereditary history was mentioned in only one case. In most of the cases the children were born alive and showed no tendency to the disease up to the time of the report, but in a few instances the babies died at varying periods after labour from a few days to five months. In four cases the birth of a macerated or stillborn fœtus took place. The mother survived in only two cases, but for how long was not determined. In many cases a prodromal period had been observed in which a pregnancy was followed by progressive emaciation, anæmia, and loss of strength from which no recovery took place, though another pregnancy supervened. Leukæmia therefore did not appear to interfere with conception. Although, judging by the recorded cases, leukæmia was a very rare complication of pregnancy, Dr. Kosmak was of opinion that a considerable number of cases of pregnancy, accompanied by marked anæmia, in which no satisfactory blood count had been made, had probably been instances of this disease. As the occurrence of pregnancy in leukæmia indicated a most unfavourable outlook for the mother, he maintained that pregnancy should not be allowed to take place when leukæmia was suspected. When the disease was already present abortion appeared to be the rule, with a rapidly progressive course and fatal issue. Owing to the harmful effect which X rays would have on the fœtus they should not be employed until after the induction of labour.

JAUNDICE DUE TO ASCARIDES.

THAT worms in the alimentary canal may give rise to toxic symptoms in consequence of absorption of toxins produced by them is now recognised. Among the toxic symptoms produced by ascarides jaundice does not appear to have been observed, though a case in which it occurred in ankylostomiasis has been recorded. At a meeting of the Société Médicale des Hôpitaux of Paris on Dec. 3rd the following case was reported by Mons. Henry Bourges. A young soldier of the colonial infantry was admitted to hospital on Jan. 4th, 1916, for anæmia, weakness, and splenic hypertrophy. For some time he had suffered from passing febrile attacks without apparent cause. On examination he was found to be wasted and there was pallor of skin and mucous membranes with a subicteric tint in the conjunctivæ. The stools were not decolorised. The spleen was enlarged and tender on palpation. The urine did not contain biliary acids or pigment, but urobilin in large amount. There was no fever at the time. Blood examination showed: red corpuscles 3,350,000 and white 16,000, of which 58 per cent. were polynuclear neutrophiles, 7 eosinophiles, and 35 mononuclears. There were a few myelocytes and nucleated red corpuscles. The "fragility" of the red corpuscles was increased. The Wassermann reaction was negative. Two ascarides were passed spontaneously. This fact, with the eosinophilia, led to the administration of santonin for three days, which was followed by the passage of 13 ascarides. But the state of the patient was not much altered. A new series of administration of santonin at intervals of eight days was followed by expulsion of 14 ascarides. Then the patient gradually improved. The pallor decreased, the conjunctivæ lost their subicteric tint, the spleen diminished, strength was regained, and appetite returned. Two months after the first examination the blood showed: red corpuscles 4,455,000, white 10,000, of which 53 per cent. were polynuclear neutrophiles, and 47 mononuclears. The "globular resistance" of the red corpuscles had increased. Thus the patient was admitted with a complete hæmolytic syndrome, which disappeared under administration of santonin. The destruction of red corpuscles could not be attributed to syphilis, tuberculosis, or malaria, or other recognised cause. The only toxic influence which could be invoked was the ascaridiasis, and its potency was borne out by the result of treatment. Ascaridiasis is now regarded as an auto-intoxication. The chemical composition of the parasites has been investigated by Mons. Fury, who has found that they contain free fatty acids, aldehydes, ether salts, and a compound previously unknown, ascaryl alcohol. Similarly, in their excretions have been found fatty acids, aldehydes, mercaptans, and ammonia. These substances not only are irritants of the mucous membrane, but on absorption produce the nervous symptoms frequently observed in those who harbour ascarides. According to Mons. Fury the non-saturated fatty acids, such as oleic and acrylic acids, are destroyers of the red corpuscles. In the case of ankylostomiasis referred to above the icterus was also hæmolytic, appeared during the anæmia produced, and was cured by administration of thymol.

QUIET HIP DISEASE.

"Benign from its onset, benign throughout its course, it tends without any treatment to terminate in almost complete functional restitution."

IN a recent monograph on "Malum Coxæ Calvé-Legg-Perthes," Dr. Halfdan Sundt,[1] medical superintendent of Fredriksvern Coast Hospital for scrofula and surgical tuberculosis in Norway, gives an account of a disease which only a decade ago was practically unknown and commonly mistaken for tuberculosis of the hip. Yet it appears to be of frequent occurrence; so frequent, indeed, that Dr. Sundt's material consists of as many as 66 cases. Most of these were sent to hospital with the diagnosis of tuberculous disease, and it is amazing to find how greatly the number of cases diagnosed as tuberculous can be whittled down by the help of modern methods of diagnosis, notably the X rays and von Pirquet's test. Indeed, it appears from the records of Fredriksvern Hospital that no fewer than 43·4 per cent. of all the cases of hip disease proved, after careful sifting, to be non-tuberculous. The recognition of "quiet hip disease"—a term given by Taylor and Frieder—as a well-defined entity has thrown much new light on the frequency and seriousness of true tuberculosis of the hip. For when these benign, non-tuberculous forms of hip disease are sorted out from cases of definite tuberculosis of the hip, this is shown to be a far more serious and far less common condition than was once thought to be the case. Hence Dr. Sundt's conclusion that all statistics which have dealt in the past with the incidence and severity of tuberculosis of the hip are hopelessly incorrect and misleading. He has come to the conclusion that when a case of hip disease clears up completely, tuberculosis can be confidently excluded from the diagnosis. One of the most instructive chapters in his monograph deals with the results of treatment, or absence of treatment. In 19 cases the patients were treated as for tuberculosis by immobilisation for one to four years, and an average of more than two years. In another group of 16 cases immobilisation or relief from pressure was prescribed for less than a year, the average duration of treatment being about six months. Finally, in a third class of 23 cases, observed over a period of nine months to 12 years, with an average observation period of more than three years, no treatment was prescribed, and the children were allowed to run about freely in spite of limping. The final results were equally good for the three classes, a finding that betrayed the unwisdom of treating these cases by immobilisation. But, as the short paper on this subject by Mr. H. A. T. Fairbank in THE LANCET for Jan. 1st shows, English surgeons have not come to the same conclusion on this point. Dr. Sundt disagrees with Perthes's term "osteochondritis" for this condition, as he believes inflammation plays no part in its genesis; this appears to be multiple, with trauma, age, sex, and predisposition playing important parts. It is to be hoped that Dr. Sundt may find a translator to collaborate with him in making this valuable monograph accessible to English readers.

FOOT-AND-MOUTH DISEASE.

THE epidemic stomatitis of cattle is a plague alike to beast and man, for while it has not a high case mortality convalescence in cows is long and capricious, and the loss of milk is as serious to the producer as the precautions against infection are exasperating. For summer after summer, in 1914 especially, many attractive Swiss passes were closed to the tourist in order that he should not carry the contagium from pasture to pasture, and in this country the embargo on importing live stock is likely to become a serious obstacle to the solution of the milk problem. The present outbreak of foot-and-mouth disease in the Midlands is unfortunately one of the worst this country has suffered from. There is a grave danger of pedigree herds of cattle and sheep (whose loss would be almost irreparable) becoming affected. Little definite has been fully decided as to the method of spread of the complaint, but it has been shown in Switzerland and Germany that the administration of sulphate of iron in the drinking-water and cacodylate of iron subcutaneously has a marked effect in reducing the virulence of an attack and in curing the disease. The milk-supply, especially in the case of children, needs watching, since the disease may be transmitted to man by raw or uncooked milk and its products. The malady, however, always runs a mild course in human adults, although in children gastric catarrh may result and even death has been recorded. The heavy mortality among Welsh sheep which recently attracted sensational notice was not attributable to foot-and-mouth disease, as investigation proved it to be due to liver rot or fluke, a disease always very prevalent after wet summers. We may well hope that the research work now being conducted on board old ironclads will soon throw some light on the habits of the contagium if not on its actual appearance, for it may well be as elusive as that of small-pox. The close clinical parallel between the two diseases has, indeed, already suggested the same kind of remedy. At the Bavarian vaccine station, Privat-dozent A. Groth has succeeded in inducing an apparently specific local disease by intracutaneous injection of material from an aphtha; in the swine and sheep the infiltrations so produced may break down and a general aphthous attack follow, but in the more refractory rabbit the infiltration may remain localised and it is hoped prove the source of a preventive vaccine. The work at all events promises well.

PROFESSOR CARL TOLDT.

A MAN of science whose publications began in 1868 with a method of injecting lymphatics, and, ranging over the fields of comparative and descriptive anatomy, embryology and histology, extend to 1915 when he contributed a note on the development of the mandible, has left a record of his life's work which needs no embellishment. Carl Toldt, Emeritus professor of descriptive and topographical anatomy in the University of Vienna, died recently at the age of 80, and his mind retained so much vigour and enthusiasm that he will be missed by his colleagues more than would many a younger man. Born at Bruneck, in the Tirol, he qualified in 1861, and after serving in the war against Italy became assistant in the physiological department of the Josepho-Akademie, later succeeding Professor Ewald von Hering as its director. In 1869 Toldt began to specialise in histology, became professor of anatomy, with charge of histological teaching in Vienna and later in Prague, eventually returning to Vienna in 1884 as professor of descriptive and topographical anatomy, an appointment which he retained for 24 years. His most famous work is connected with the mandible and its surrounding structures and his best-known publication, at least outside his own country, is the Anatomical Atlas, which appeared in 1896–1900. Since his retirement Professor Toldt had been chiefly concerned in anthropometrical investigations and the study of prehistoric forms of man, and his observations in this region of knowledge were no less sincere and important than his contributions to descriptive anatomy.

MEMORIAL TO THE LATE DR. A. J. CHALMERS OF KHARTOUM.

THE late Dr. A. J. Chalmers, the well-known authority on tropical diseases, and joint author with Dr. Castellani, of "Tropical Medicine," whose sudden death on his way home on leave in April last was a great loss to the profession and his numerous friends, left a splendid collection of medical books, mainly on tropical diseases, and including some almost priceless incunabula. The whole of these, with the exception of a small number presented to the Royal College of Physicians of London, have been given by Mrs. Chalmers to the Royal Society of Medicine. The Society has wisely decided that the collection shall be kept together and be known as the "Chalmers Collection," and now we are informed that Mrs. Chalmers has presented the Society with the sum of £500 for the shelving and furnishing of a room in which the books will be kept as a memorial of her husband. It is hoped that the collection will be added to from time to time, and the room chosen for the Chalmers Library is well adapted for the purpose.

This admirable donation coincides happily with the reconstruction of the new Section of Tropical Medicine and Parasitology. The Section was formed in 1912, but was suspended during the war, and has only this session been formally constituted, and among the first nominated officers are Lieutenant-Colonel Sir Leonard Rogers as President, and as Vice-Presidents, Professor Leonard S. Dudgeon, Lieutenant-General Sir John Goodwin, Vice-Admiral Sir Robert Hill, and Professor G. H. F. Nuttall. That all these at once accepted office is a good omen for the success of the new Section. Sir Leonard Rogers recently presided over the first meeting of the new Section, when an exceptionally interesting programme was provided,[1] and we are now able to congratulate it on starting with a library of its own, which is probably the finest collection of books on tropical medicine to be found.

BY an Order in Council, dated Dec. 21st, 1920, it is enacted that the Order of Jan. 7th, 1915, shall be revoked without prejudice to the right of any persons whose names have been already entered on the Register. The Kingdom of Belgium no longer affords to the medical practitioners of the United Kingdom such privileges of practising in Belgium as were offered during the late war. Practitioners possessing Belgian qualifications are, therefore, no longer entitled to registration in the Medical Register of the United Kingdom.

---

[1] THE LANCET, Dec. 11th, 1920 (p. 1193).

THE Ki[illegible]-Edward Hospital Fund has made a grant of £1[illegible] the Devon and Cornwall Sanatorium for Consumpti[illegible], on condition that eight beds are reserved for [illegible] of King's College Hospital, Guy's Hospital, and [illegible] City of London Hospital.

THE FUTURE OF THE DROITWICH BRINE BATHS.

(FROM OUR SPECIAL COMMISSIONER.)

Droitwich, December, 1920.

THOUGH the statistics might have been more carefully kept and more extensive there can be no doubt as to the excellent results often obtained from the brine baths of Droitwich. The nearest approach to a record on an extensive scale will be found at the St. John's Brine Bath Hospital, a charitable institution supported by voluntary contributions and erected in 1892. Here there is room for 24 male and 17 female patients. Till recently the treatment was, with some exceptions, limited to two weeks, and under these conditions the figures for ten years show that an average of 650 patients have been treated per annum. The secretary of this hospital has informed me that, after 25 years of personal experience, and on records kept from time to time, the result would show that 75 per cent. of the patients obtained permanent benefit. But it should be noted that of the 25 per cent. who received no benefit several received no treatment. In the course of a day or two it was discovered they were afflicted in a manner which the treatment could not alleviate—malignant growths or certain forms of skin disease—and they were therefore at once sent away. The hospital is only intended for the treatment of gout, sciatica, rheumatism, and kindred complaints. During the war, and as a result of the hardships endured in the trenches, many soldiers suffered in these ways, and no less than 50,000 baths, free of cost, were given to officers and men serving mostly in the army, but occasionally in the navy. Mr. Hollyer, the general manager, converted his private house into a convalescent home for 20 officers. Then a hospital with 40 beds for private and discharged soldiers was opened, and the War Office expressed the thanks of the Army Council for this generous and whole-hearted attention, which proved of great practical value.

Opportunities and How to Meet Them.

Evidence and statistics might have been collected on a much larger scale, giving more conclusive figures as to the benefits of the brine-bath treatment. Not that there is any lack of such evidence. Piles of letters are forthcoming from grateful patients, but there has been no centralised and systematic effort to group the facts and give a summary of the results. In this, as in other respects, Droitwich has trusted too much to individuals and has somewhat neglected to organise collective effort for the common good. As a consequence magnificent opportunities were lost. None could have been more evident than that created by the war when so many patients were unable to go to the continental thermal stations they were in the habit of frequenting. That was the moment when all the citizens of Droitwich should have gathered together and insisted on organised action, and when, it might be thought, medical men would have seized the opportunity for study afforded by a large number of patients, more or less belonging to the same class, suffering under conditions brought about by circumstances common to them all. The stress caused by the war, the need to unite every effort to relieve the wounded, and the acknowledged services, in so many cases, which the brine baths at Droitwich had been proved to render—these things would have rallied both Government and public to the support of some practical scheme to convert Droitwich into a national asset, if such a scheme had been brought forward. In this spirit Droitwich fully participated by giving free baths, free hospital treatment, and friendly sympathetic hospitality to the war victims. But there the movement seemed to stop; yet there was so much to follow. The war has ceased, but the consequences of the war are only beginning to be fully understood, and will only be met by broad national efforts such as those which won the war.

So far well-to-do private patients, who can pay for all they require, are generally able to take sufficient care of themselves. Nevertheless, they are fully entitled to ask why a place like Droitwich cannot be brought up to the level in ordinary amenities which many continental spas have attained. In such places the hotel manager participates in the actual treatment. The patient's medical adviser sends his prescriptions round not only to the dispensing chemist but also to the hotel manager, who has to be prepared willingly to provide any special diet considered desirable. Indeed, all *the hotel and lodging-house keepers should be grouped* together and periodical lectures given to explain how they can best second the efforts of the medical profession to cure the patients and thus contribute to improve national health and local prosperity. If hotel managers consider patients who need special diet too much trouble and strive to get rid of them, they must not be surprised to find that preference is shown for continental spas. British hotel-keepers, especially in a place which has legitimate aspirations to be considered a health resort, have got to learn that they are engaged in a national work, and that the resources of this country ought to be developed for the sake of all. Incidentally they would put money in their pockets. More baths, more houses, more enterprise, are wanted. It is not because some enterprises are paying concerns that nothing further is to be done. By all means let those engaged in the business earn good profits; but *the first consideration is that the nation should be able* to avail itself of the healing qualities of the Droitwich waters. As matters now stand, striking cures are effected, but the advantages of such cases to the reputation of Droitwich are often lost because the facts are insufficiently known, and there is not the necessary accommodation for a large increase of patients.

The Housing Difficulty.

The main or the most immediate problem is the housing problem. It presents the same aspects here as everywhere, but I may be excused for setting it out, as it shows how in numberless other places, as well as at Droitwich, the obvious needs of development cannot be immediately met. More houses and more baths are urgently wanted at Droitwich; but at the present cost of building it is difficult to find anyone ready to risk the necessary outlay. There is a Government scheme for the construction of 56 houses, which have to be completed by June, 1922. Of these 16 have already been erected. They are all to be working-class cottages and none are to be let at a higher rent than 8*s.* a week, *which, it is calculated,* will not represent more than 2 per cent. on the capital outlay, if estimated at the present cost of building. Also these houses must not be rated at more than 1*d.* in the £. So that the State stands to be a heavy loser, while it is thought that this will not increase, but will more probably check, speculative building. In any case these 56 cottages are to be let for less than half the rent that should be paid to cover the cost, and the question is asked who are to be the privileged tenants. Yet and whatever the answer may be to this question, it is but a detail, for something on a much larger scale is needed.

It is a matter of national importance to preserve the health and strength of all those who by productive work are helping to rebuild British prosperity. Curing the sick is but a small part of the problem before the Ministry of Health, though newspaper critics are clearly blind to the fact. The prevention of sickness and its remedy in early stages are the great desiderata. One of the real benefits of the compulsory system of insurance is that it enables the poorest sections of the community to seek medical advice at a much earlier stage of the disease. At Droitwich local practitioners expressed the opinion that anyone who has suffered from some rheumatic complaint of sufficient severity to be laid up for two or three weeks should take a course of brine baths as a preventive against other and more severe attacks of a similar nature. Certain it is that many patients would have given themselves a much greater chance of complete cure had they commenced the treatment at an earlier stage. It is not as a last hope that patients should come to Droitwich, but rather as the first form of treatment, and this will only be largely available when building, reconstruction, and coöperative organisation are set going.

Spa Treatment on a National Scale.

These considerations open out a gigantic problem for so small a place as Droitwich to handle. There were 11,500,000 persons entitled to medical benefit under the Insurance Act in 1919, and it will probably be found that the number has been increased by about a million in 1920. There were, in 1919, *in England and Wales*, 20 million weeks of unfitness for work among insured persons. If only a very small proportion of these 20 million weeks of sickness were spent at Droitwich what a colossal undertaking this would represent for so small a place. Yet there is nothing new or out of the way in such a suggestion. It has been done, done for years and very successfully, but, of course, only on a small scale. Still, shall it be said that what a few workmen have been able to achieve for their own benefit cannot be accomplished on a much larger scale *by the united forces of the entire nation?* In both cases the position is identical; the only difference is in the number of persons involved. This is what happened. When the St. John's Brine Bath Hospital was first started every person who subscribed a guinea per annum had the right to send a patient, who was admitted in his turn. The patient had to pay 10*s.* a week for his maintenance, and received medical advice, complete board, and the necessary baths for a fortnight. These rules have now and quite recently been altered. The voluntary subscription has been *raised to 3 guineas, and the time of treatment to three* weeks. But these are only details that do not affect the principle, for this depends not so much on the amount paid, but on who it was who paid. Now, in this respect, the remarkable fact, that cannot be too carefully noted, is that the hospital, in the earlier stages of its existence, owed its success mainly to the Hearts of Oak Friendly Society. Here, then, we have, on a smaller scale, conditions similar to those that obtain under the Insurance Act. A sick fund is created by small weekly subscriptions, when experience demonstrates that, *by sending some of the patients to* Droitwich, they were sooner able to return to work. Thus the amount of sickness and the drain on the sick fund is reduced—a double saving, which other similar institutions soon learnt to appreciate. Sick funds established in large works or factories began to send some of their patients. This was notably the case at Coventry. The Birmingham Saturday Hospital Fund has now a beautiful convalescent home at Droitwich with some 60 beds. The benefit societies have found it cheaper in the long run to send their patients here. Then what *about the panel patients? Is there not a saving to be* effected with them on what might be called a national scale? This would undoubtedly be the case, especially if a large number of patients could be sent sooner. Here are the means of economising health and money; all that is needed is the power of organising and the initial outlay, to be ultimately refunded. It is not a question of spending money, but, by reducing the prevalence and duration of sickness, of saving money. What the Hearts of Oak Club has satisfactorily demonstrated on a small scale it should be for the Government and the public to assist in realising on a national scale.

The waters of Droitwich are recognised as the strongest natural brine in Europe. They contain more than 20,000 gr. of chloride of sodium per gallon. They also give off radio emanations, which *the patients inhale* while bathing. The curative and tonic properties of these waters have been proclaimed by numerous competent authorities. Such a source of health and wealth should be developed to the uttermost, and not be allowed to languish for want of enterprise. Droitwich deserves to acquire popularity equal to that of the best continental balneological resorts.

MANCHESTER ROYAL INFIRMARY.—A tablet to the memory of resident surgeons of the Manchester Royal Infirmary who were killed during the war is to be placed in the main entrance of the building. The cost, about £100, will be defrayed out of the Medical Board Fund.

in 1864, and after serving in the war against Italy became assistant in the physiological department of the Josepho-Akademie, later succeeding Professor Ewald von Hering as its director. In 1869 Toldt began to specialise in histology, became professor of anatomy, with charge of histological teaching in Vienna and later in Prague, eventually returning to Vienna in 1884 as professor of descriptive and topographical anatomy, an appointment which he retained for 24 years. His most famous work is connected with the mandible and its surrounding structures and his best-known publication, at least outside his own country, is the Anatomical Atlas, which appeared in 1896-1900. Since his retirement Professor Toldt had been chiefly concerned in anthropometrical investigations and the study of prehistoric forms of man, and his observations in this region of knowledge were no less sincere and important than his contributions to descriptive anatomy.

MEMORIAL TO THE LATE DR. A. J. CHALMERS OF KHARTOUM.

THE late Dr. A. J. Chalmers, the well-known authority on tropical diseases, and joint author with Dr. Castellani, of "Tropical Medicine," whose sudden death on his way home on leave in April last was a great loss to the profession and his numerous friends, left a splendid collection of medical books, mainly on tropical diseases, and including some almost priceless incunabula. Such a source of health and wealth should be developed to the uttermost, and not be allowed to languish for want of enterprise. Droitwich deserves to acquire popularity equal to that of the best continental balneological resorts.

MANCHESTER ROYAL INFIRMARY.—A tablet to the memory of resident surgeons of the Manchester Royal Infirmary who were killed during the war is to be placed in the main entrance of the building. The cost, about £100, will be defrayed out of the Medical Board Fund.

HYGIENE ON THE SEA:

ACCOMMODATION FOR SEAMEN IN SHIPS OF TO-DAY.[1]

(BY OUR SPECIAL CORRESPONDENT.)

VI. A UNITED STATES PASSENGER LINER.

THE *Panhandle State* (10,553 tons), of the United States Mail Steamship Company, was lying in Tilbury Docks when I found her. She is quite a new ship, laid down during the war, twin-screw and oil-burning. She only carries 120 passengers, all in the first class, and all in the midship superstructure. Captain Cunningham, Dr. Robert, and her officers were most kind and anxious to take me to all of their ship, of which they are naturally very proud.

Passenger Accommodation.

The cabins, all outside, vary a little in size, but are, every one of them, quite commodious. The standard equipment is two beds, each with a shaded reading light at the bed-head, so that one can read without disturbing a cabin companion; there is a fixed basin with hot and cold water, and alongside it a thermos flask of iced water. Each passenger has five small drawers for necessaries of the voyage. In the larger cabins there is a settee with two longer drawers underneath it. There is artificial supply of air, an electric fan, a steam heater, and a wardrobe. Half the cabins have private bathrooms; there are also public bathrooms and over each bath is a douche, with mixer, so that the temperature of the shower is regulated at will. The saloon, at the fore end, is fitted with tables for four people each and with excellently pivoted chairs. The saloon is heated with hot air. Behind it is the pantry, directly over the kitchen, in which the cooking is done either by steam or on an oil-fired range; oil is said to be as great an improvement on coal in the kitchen as it is in the stokehold. Outside the kitchen is a bakery, where the dough is all made by an electric kneader, beyond that the butcher's room, steward's store, &c. There is also a laundry, with much machinery, but idle, because unneeded on this short run. The passengers have a music room or social hall (piano and gramophone), a smoking room (also with a piano), and a verandah café at the after end where they can sit on deck and yet be out of the wind; also there are two promenade decks, one enclosed in all its length, with sliding glass windows, so the passengers are not badly off. The officers, too, are well looked after and have plenty of room in their cabins, and these are well furnished. They also live in the superstructure, a deck or more above the passengers.

The doctor is very nicely treated. His suite is at the corner of the superstructure, portside aft. His sleeping cabin is right aft, his bathroom, basin, and w.c. are along the portside, behind a partition, and his office or surgery, between sleeping cabin and lavatory, opens off the passenger's alley-way. There is a large dispensary cupboard in the office, but the space is not much encumbered, though the furniture is "good and plenty." Another door in this bewilderingly large cabin gives access to a staircase leading to the crews' quarters, so that everyone can easily reach the doctor's office, passengers from one side and crew from the other, without crossing one another. Very well planned all of it, making first-class accommodation for a medical officer.

Seamen's Quarters.

The accommodation for the sailors is in keeping with that for the officers and passengers. It is such as I have never before seen. I was first taken to the sailors' mess place, it is amidships, not far from the kitchen. It had a mess-table for 12 men. I suppose it was 12 feet high, 10 feet wide, and 14 feet long; 140 cubic feet per man for the 12 men who messed here. There was the appropriate mess-rack and dresser, also a steam table for keeping food hot, with a cupboard below to warm the plates. This for 12 men, and similar equipment for every mess in the ship. Besides on the dresser there was a steam coffee machine, the same pattern as in first-class passengers' pantries in English lines, and coffee free for the sailors all day and all night long for the turning of a tap. I was curious to hear how much coffee this meant, and was told that 2 oz. daily, 1 lb. a week, was, in practice, the expenditure per man. There were similar messes for petty officers and for the engine-room staff. There are lavatories for firemen, with douche and two fixed basins, so far as I can remember exactly the same as for the first-class passengers. In their w.c. I found a roll of latrine paper, provided apparently by the public conscience of the messes. Next I came to the firemen's sleeping berths: they are cabins for three men. The first I estimated as 12 feet high, 6 feet long, and 10 feet broad; this works out at 240 cubic feet per man, and in their sleeping place, quite apart from the 140 cubic feet each I have mentioned in the mess places, apart also from the bathroom accommodation, both of which are included in the English official 120 cubic feet per man. I expressed some surprise at this generous allowance, so much larger than any I had ever found, and doubted my calculation, but was assured that 240 cubic feet was all right, that being the legal minimum for a member of the crew in an "American" ship. And this firemen's cabin was not bare. Besides the bed places (iron), one single, one double-tiered, there was a toilet-rack for tooth and shaving brushes, little cupboards in it too, a looking-glass for each man, and a steel clothes locker of the pattern so familiar in U.S. factories; it varied in size according to the position in which it must be placed, but a standard size would be 6½ feet high, 10 inches wide, with a shelf across about 1½ feet from the top and below that hooks for clothes. The steel door has three ventilating louvres and is secured by a padlock. There are many hooks about the walls for the men's other clothes. There is an electric fan, and plenty of electric light, which spreads its effect widely because the cabin is so lofty, and there is a good heater.

Baths and Lavatories.—Hospital.

The sailors of the crew are berthed in a deck-house aft, and their accommodation is quite similar. They have a bathroom and lavatory, painted, not white, as I like, but a light slate-blue, and no abominable brown or yellow dado. The showers supply warm fresh water, and the men have plenty of room. The stewards' accommodation is on the deck below and is very similar. There are some 40 stewards, and they have two douches of their own. The hospital is right aft, astern of the deck-house for the crew. There are four beds, double-tiered, and the operating-table is amidships; the whole well lighted. There is a fixed basin with water steriliser and a w.c. Here I got a surprise. I had seen baths, basins, w.c., &c., throughout the ship, and had taken them for ordinary white earthenware and good of its kind, but happening to say so when in the hospital I was told I was quite mistaken. They were one and all of iron, porcelain enamelled, the enamel baked on. Lighter, cheaper, and less breakable than earthenware, and giving exactly the same security for cleanliness and the same decorative effect. The only fittings in the ship I should like to see changed are the w.c.'s for the crew; they are not well-shaped and are less easily flushed therefore, nor so well enamelled and smooth. That such a complaint should alone emerge seems to suggest that the rest of the ship was very good. Besides, I did hear there was some thought of replacing these w.c.'s by a better pattern.

Coming away from the hospital I noticed what the French call a *gouttière*, a gutter stretcher of steel frame with wire netting over, for moving and perhaps for hoisting out a lying-down case. It had a short pillar to steady the patient by the perineum, and the necessary hand-holds, also serving for securing bandages or the slings for hoisting a patient out. I mentioned the gyroscope compass on the bridge of *Imperator*. On board the *Panhandle State* I was shown the gyroscope itself, in a special compartment, the gyroscope room. There are two gyroscopes—heavy wheels revolving 10,000 times a minute; they are fixed parallel in a frame, and as each when revolving takes up its position with its axis parallel to the axis of rotation of the earth, the line between the poles, the index of the frame points always to the north, and is not diverted by the local variation or the quadrantal or other deviation of the ship, and one of their great anxieties is off the navigator and the captain. The ship has a very delicate "wireless" receiver in which the officers are much interested. I was allowed to listen, and heard quite distinct clicks, which they told me were signals from a wireless station in the United States. This at 4 P.M. at Tilbury.

---

[1] Previous articles which have appeared in THE LANCET describe the accommodation on *Aquitania* (Sept. 11th, 1920), *Olympic* (Sept. 25th), *Imperator* (Oct. 9th), *Achilles* (Nov. 27th), and Cargo Steamers (Dec. 18th).

Summary.

On her small displacement this ship does more for her officers and crew than any ship I have seen up to the *Aquitania* and *Olympic*, five times her size. The men are treated more kindly than in any English lines. They ship at New York for the voyage or for six months, whichever is the shorter. When they return to New York they are discharged, but any man who wants to go on again, and is appreciated, signs on again next day. Service for approved men is thus practically continuous. That means no boarding-house bill, fewer temptations, more saving. This ship is not a charitable institution but a business proposition, and I therefore feel emboldened to impress on British shipowners that other people can give their crews better accommodation, free coffee all the time, and continuity of service, and will find it pay to do so. Also, that they can lodge their doctor comfortably; doubtless the owners get a more skilful surgeon who gives them better service.

I must express my thanks to the U.S. Mail Steamship Company for kindly letting me go on board this very interesting ship. I expected to find something rather good in accommodation for sailors on board a United States ship and I was not disappointed.

CONTROL OF VENEREAL DISEASE.

The Dangers of Half Measures in Syphilis.

PUPILS of Cæsar Boeck, late professor of dermatology in Christiania, used to speak almost apologetically of his antagonism to the exhibition of mercury in syphilis. He argued that, particularly in early syphilis, mercury is apt to modify the reaction of the organism to the invader, and by rendering the course of the disease atypical do the patient more harm than good. At the time his distrustful attitude towards mercury was rather contemptuously condoned as the foible of an otherwise gifted scientist. Now, however, there seems to be a growing conviction that timid specific treatment with mercury or salvarsan may divert the disease from other parts of the body to the central nervous system. At a recent meeting of the Medical Society in Christiania Boeck's successor, Professor Bruusgaard,[1] discussed two series of cases which throw light on this point. The first included the 630 cases of early secondary syphilis treated at the Dermatological Department of the Rigshospital in Christiania since 1912. Among these were ten cases of neuro-recurrence, and a feature common to all was the timidity, dilatoriness, unmethodicalness, and general inadequacy of the specific treatment they had received. In one of these cases there were signs of meningeal irritation early in the disease which terminated fatally 16 months after infection. The lepto-meningitis found post mortem was, in Professor Bruusgaard's opinion, undoubtedly fostered rather than checked by the few intramuscular injections of salvarsan which were given at long intervals. His second series of cases, a total of 420, concerned patients with early secondary syphilis treated since the summer of 1915 with large doses of salvarsan and mercury. In this series there was only one case of neuro-recurrence, the patient being a workman, aged 20. The cerebro-spinal fluid was normal on his admission to hospital. He was discharged, after a combined course of salvarsan and mercury, symptom-free and with Wassermann's reaction negative. A month later he reappeared with signs of severe syphilis of the brain. Had he but examined the cerebro-spinal fluid before the patient's discharge, Professor Bruusgaard thinks this disaster might have been avoided, as the evidence of lumbar puncture would probably have indicated further treatment. Though he attaches great importance to pushing specific remedies to the utmost, he recognises conditions under which the affinity of the poisons of syphilis for the nervous system may be so great that, with the best of care, the disease is apt to settle in the nervous system, thwarting the most heroic efforts to dislodge it. The figures given in this paper certainly suggest that neuro-recurrence is more common after casual than after systematic and vigorous treatment, but they do not show that syphilis of the central nervous system is more common after casual specific treatment than in the absence of any treatment. In the nature of things this point must be difficult to settle by statistics, for to control specific treatment by a comparison of treated with untreated cases involves unjustifiable methods.

The German Association for Combating Venereal Diseases.

A pamphlet issued by this Association, and recently received by the N.C.C.V.D., to which we are indebted for the following notes, gives in brief space a comprehensive review of its history, ambitions, achievements, and, perhaps most instructive of all, its failures. The Association has now been at work for over 16 years, and to judge from its candid survey, its activities have grown rapidly, and its sphere of usefulness has been greatly enlarged. The original objects of the Association were the recruiting of the greatest possible number of members from all strata of society, the formation of branch associations, convening of meetings and giving of lectures on sexual hygiene, distribution of popular educational literature, direct and indirect exercise of pressure on legislative bodies, reform of the treatment of venereal disease, supervision of prostitution, sympathetic contact with the daily press, and the founding of a special journal. Altogether an ambitious programme. It was soon found that educational propaganda was the first and most essential need; ignorance as to the dangers and consequences of infection proved to be enormous. But the wording of educational propaganda was at first a serious stumbling block, for marked differences of opinion arose as to: (1) the effect of sexual continence on health; and (2) the morality and tactical wisdom of advocating prophylactic measures. The upshot of these differences appears to have been a compromise; the exact nature of this compromise is not disclosed, but is said to be "tactful." Many millions of pamphlets have been published for the guidance of men and another pamphlet has been published for the benefit of women, in which both the hygienic and ethical aspects are emphasised. It was, however, found that the information given in these short pamphlets was too sketchy and more elaborate publications were called for. These proved useful as material for popular lectures and instruction of children by their parents. Pictorial propaganda in the form of lantern slides and cinema productions have also been pushed with vigour and success, and a travelling exhibition has also proved very effective. The translation of Brieux's play, *The Shipwrecked*, by Professor Flesch, was a considerable but not complete success when staged in Germany; its dramatic force made a deep impression, but from the artistic standpoint it was faulty. Many hundred thousands first learnt of the importance and great dangers of venereal diseases through this play. It was also filmed under the title of *And There Was Light*, but it had to be confessed that the artistic blemishes were emphasised on the film, and the educational utility of the work was largely obscured by side issues dragged in by producers anxious to add to its commercial value.

So far the efforts of the Association to introduce sex hygiene into the curriculum of schools of various grades have met with much passive obstruction and have been fruitless. But its original ambition to publish a journal in which every aspect of the problems involved could be discussed from every point of view has materialised in 16 volumes of *Mitteilungen der Deutschen Gesellschaft zur Bekämpfung der Geschlechtskrankheiten*, and in 18 volumes of the more scientific publication *Zeitschrift für Bekämpfung der Geschlechtskrankheiten*. An example of the usefulness of these publications was their free ventilation of the problem of infection conveyed to their homes by discharged soldiers. This discussion prompted the establishment of consultation centres and dispensaries for venereal disease in many parts of Germany.

---

[1] Norsk Magazin for Lægevidenskaben, November and December, 1920.

In the field of legislative reforms the activities of the Association appear to have been numerous. Its agitation against penalising insured persons suffering from venereal disease and disqualifying such persons for insurance benefits quickly led to reforms. The Association has also made its influence felt in legislative measures dealing with such matters as the sale of preparations supposed to prevent conception. It has also succeeded in extending the obligations of professional secrecy, incumbent on doctors, to officials employed in the administration of sickness insurance. Further, its interest in the problems of prostitution led to its appointment of an independent commission of experts whose recommendations were largely reflected in the Bill submitted to the Reichstag in 1918 on the control of venereal disease. Much has also been done by the Association to get venereal disease treated as a specialty by specialists. It has also secured chairs at certain universities for venereology which has become a compulsory subject for examinations in medicine. It would thus appear that many, if not most, of the reforms carried in Germany with reference to the venereal diseases have been instituted by *Die Deutsche Gesellschaft zur Bekämpfung der Geschlechtskrankheiten.*

Prophylaxis in a Texas Camp.

In a recent number of the *Military Surgeon* Captain T. Hall, of the Sanitary Corps, U.S. Army, presented a summary of the reports on the 10,000 cases of venereal disease notified to headquarters between Sept. 10th, 1919, and Sept. 13th, 1920. Amongst them there were, per cent., 66 cases of gonorrhœa, 21 of chancroid, and 13 of syphilis. It may be noted that in 1914, the last year for which statistics are available, the figures for the British Navy were almost the same—68, 22, and 19—amongst some 8000 cases. In the American Army the prophylaxis of venereal disease seems to be increasingly, though only slightly, justifying itself. The town from which most cases (456) are reported is in Texas, four miles from a great camp, and the second paper is a particularly interesting account of prophylaxis at that camp. In an account, which will well repay perusal by all who are engaged in minimising the disasters of venereal disease, Major C. W. Shaffer, Medical Corps, U.S. Army, who was sanitary inspector of the second division, quartered in that camp, describes the measures he took between January and July, 1920, to draw the men to avail themselves of the prophylaxis offered them. He desired to get prophylaxis taken and to get it taken early. There was a treatment centre already in the town, but it was out of the way. He got space in an army hut, close to the centre of the town, near the theatres, and near the station from which the trams and 'buses started for the camp. Men on pass would not leave the town early in the evening to go out to the camp for treatment and lose the rest of their leave; so he brought treatment to them and they took it. He had a very neat equipment installed, had a trustworthy orderly always on the spot, and saw that the place was kept as perfectly as an operating room. The orderly saw disinfection thoroughly done, otherwise each man had complete privacy for his ablutions. The equipment and the minute routine of treatment, both very judicious, must be read of in the paper. The men reacted to this care for them; 10 was the approximate number per night, but 63 were treated on one single evening. In all 1361 men were dealt with in six months. Of these, 572 belonged to the camp, so that their history could be followed. Amongst them there developed only 3 cases of disease, and it is suspected that these came late for disinfection. Major Shaffer tried tactfully to get the men to take treatment and was successful; he tried to get treatment taken early, and here again he had success. How little weighs his trouble, the cost of the equipment, and the wages of the orderlies, how little they all are compared to the damage to the nation and expense to the army of the possibly 250 additional cases of venereal disease saved in six months in the town which in this year inflicted 456 cases on the United States Army.

The All-America Conference.

The Washington Conference last month was attended by over 400 delegates, there being representatives from Argentina, Brazil, Chile, Ecuador, Cuba, Honduras, Mexico, Paraguay, and Porto Rico on the New World side. Canada was officially represented by Dr. John A. Amyot, deputy Minister of Health. Sir Arthur Newsholme was put down as English representative, although he still occupies a chair at Baltimore. Dr. T. F. Ritchie, Lieutenant-Colonel, R.A.M.C. (retired), came from the League of Red Cross Societies. Czecho-Slovakia sent two delegates.

The conference is described as one of the most remarkable medico-sociological gatherings ever held in America. A General Conference Committee was selected by the president, Professor Wm. H. Welch, on the nomination of the Administrative Committee, to include pathologists, bacteriologists, syphilographers, urologists, gynæcologists, general clinicians, statisticians, clergymen, educators, psychologists, psychiatrists, sociologists, law enforcement officers, social service workers, and others. At the first meeting of the Conference they were divided into 12 groups, each dealing with a special group of problems, presented in the form of questions previously prepared by the Administrative Committee. At the afternoon session each section chairman reported for general discussion the conclusions arrived at by his section in the morning meeting. These discussions often showed that conclusions quite valid from the restricted view-point of one section had to be modified considerably to meet the requirements of other sections or of the entire committee. In some instances conclusions presented by one section and sharply combated by members of another section were referred to a joint meeting of the respective sections and of such others who were interested with instructions to submit a report on the following day. In other instances conclusions presented to the General Conference Committee by one section were adopted with little or no change.

In this way a number of conclusions were reached by the whole Conference, of which the following were noteworthy:—

Immunity.

With *reference to gonorrhœa*, there is no evidence of the establishment of any immunity to disease beyond that of a more or less temporary immunity in the case of existing individual infections. Such a temporary relative immunity may be lost either as the result of disturbed relations between the infecting organism and the host or through the introduction of a new gonorrhœal infection.

With reference to *syphilis*, there is no evidence of an absolute and permanent immunity to syphilis unless it be that due to an existent infection. There is evidence to show that *infection* may exist without obvious manifestations of the disease. The immunity ensuing in such an infection may extend even to the degree of a commensal or symbiotic adaptation.

Wassermann Reaction.

The blood Wassermann reaction should not be used as a sole guide to the duration of a syphilitic infection. The blood Wassermann reaction should not be used as the sole evidence of the effectiveness of a *particular drug or method of treatment.* The blood Wassermann reaction should not be used as the sole evidence of "cure," no matter how many times repeated.

The complement-fixation test has not yet been shown to be of value in the diagnosis of doubtful cases of gonorrhœa. It is possible, however, that the precipitin test recently reported by Meader and Robinson may be of great value.

Venereal Disease Clinics.

The treatment of venereal diseases in the same institution with other diseases promises a better understanding on the part of young physicians, especially among interns and medical students, regarding the importance of these diseases and of the true relation established between them and other pathological conditions.

Education.

Fear should not be deliberately stressed as a deterrent. The element of fear should appear only to the extent that it is inherent in the presentation of the facts themselves. Any morbid tendencies resulting from such unavoidable fear should be corrected by positive and constructive teaching as to the prevention and cure of the disease.

Law Enforcement.

The establishment and maintenance of high standards of sex conduct is the best protection of public health from venereal diseases. Up to the level of the highest standards which can be sustained by public opinion, laws penalising the promotion of, and the indulgence in, illicit sex relations, constitute sound and practicable public health measures.

The establishment of reformatories with standard equipment for examination, classification, training, recreation, and parole is the most hopeful method of rehabilitating the old offender.

Psychological Aspect.

Although there is danger that a superficial and erroneous interpretation of the Freudian psychology in regard to the repression of the sex instinct may be detrimental to the successful development of the programme for the control of venereal disease, a more thorough-going, complete, and scientific interpretation, however, tends to aid such a programme, in that it places the emphasis upon the practical means for guiding the sex instinct into socially useful and constructive activities.

A detailed account of the proceedings is in course of preparation.

HOUSING NOTES.

The Government Building Scheme a Success.

IN spite of shortage of labour, and especially of skilled labour, very considerable progress has been made with the Government housing scheme during the last 12 months. The extent of the difficulty caused by the shortage of labour can be gauged from the following approximate comparative figures for England and Wales as to labour in the whole building trade:—

	1910.	*1911.*	*1914.*	*1920.*
Masons ...	73,012 ...	52,188 ...	34,381 ...	19,310
Slaters... ...	9,706 ...	8,391 ...	4,154 ...	3,673
Plasterers ...	31,301 ...	25,082 ...	19,479 ...	12,067
Joiners ...	265,000 ...	208,995 ...	126,345 ...	103,199
Bricklayers	*115,995* ...	*102,752* ...	*73,671* ...	*53,063*

Steady progress has been made in private building, aided by the Government subsidy. In April last the grant was paid to the builders of two houses; now money is paid each week in respect of 300 completed houses; in nine months 4443 houses built by private builders have been completed. Under schemes of local authorities and public utility societies 11,122 houses have been completed, as compared with 848 in January last. Some 60,000 houses were commenced in 1920. The London region has up to the present exceeded all the others in the number of houses built and certificates applied for under the grant to private builders. These figures speak for themselves.

Building by Direct Labour.

The Ministry of Health has required the Metropolitan Borough Council of Poplar to accept the lowest tender for housing work rather than build by direct labour at a slightly higher cost. Much is to be said in favour of the Ministry's decision. There is perhaps a likelihood, if building by direct labour is carried out by a municipal corporation, for the workmen to make demands which would not receive the support of the general public; men working for a municipal council are at times apt to think they can impose conditions which a private contractor would not entertain. This is one of the weaknesses of local government; a councillor's seat of course depends on his retaining the suffrages of his constituency, and a section in his ward at times obtains an undue ascendancy in voting power. It is often stated that building by direct labour has very considerable advantages over building by ordinary tender; in several instances within the writer's knowledge direct labour has not been the only factor in the problem which has rendered such a course advisable. The authority has, through the energetic action of one or more of its members and officials, taken advantage of offers to obtain building materials at favourable prices when the opportunity presented itself, although they were not requiring such materials for immediate use. This is, of course, an argument for granting chairmen of committees reasonable executive powers. But it is also well known that a private contractor can usually buy much cheaper than a public body; unless a public conscience is awakened among the commercial members of the community generally this state of affairs will continue.

Houses Built of Concrete.

No subject has been of greater interest to the public in connexion with building than the use of alternative new methods of construction. Cement concrete is the material which seems to the layman to be the most obvious substitute for brick. H.M. Office of Works has obtained the sanction of the Richmond (Surrey) Town Council to erect in concrete a number of houses in connexion with the municipal housing scheme; Pattinson's process will be employed. This patent shuttering system provides a hollow concrete wall with 4-inch inner and outer casings and a 1¾-inch cavity; houses of a similar type are in the course of erection in Bedford. Although this form of construction cannot be condemned on the ground of instability, to produce a satisfactory structure much depends on the careful mixing of the materials in correct proportions; the complete filling of the shuttering requires careful workmanship and close supervision. H.M. Office of Works provides a working foreman who has had experience of the making of houses by this method; when he has imparted his knowledge to one or more of the workmen engaged in the erection of these concrete houses he passes on to another area where his services are needed. The Building Board appointed by the Scientific Industrial and Research Society is carrying out experiments on a site allotted at East Acton for practical research as to the best and most economical means of erecting cement concrete houses. It would seem that the committee has formed the interim conclusion that wooden shuttering enabling a cavity wall with iron ties to be built constitutes a practical proposition. It is doubtful if anybody is in a position to compare houses built of cement concrete with those built of brick; the stability of both the concrete and brick depends in a large measure, if not entirely, on the care and skill with which the foundations are laid. If more or less superficial cracks appear in the concrete walls these can be patched up. As the cement houses built for the Richmond housing scheme are to be covered with rough cast the addition of more of this material will prevent any trouble arising from cracks. Even in houses constructed of brick an unsightly appearance caused by aqueous vapour in the air condensing on the walls (water of condensation) is only too frequently found; by adding a proportion of coke-breeze to the material used to make the inner wall of the concrete houses it is expected that in this particular these houses will compare very favourably with the usual house built of brick; if the inner wall is finished with plaster instead of cement an additional safeguard against water of condensation is provided. A builder who in 1870 erected at Folkestone on the lower sea-front a crescent of 14 houses built entirely of cement concrete claims that concrete houses cannot be equalled for warmth in winter, coolness in summer, dryness, and being soundproof by any brick house of the same age; he holds that their solidity increases each year with their age, as shown by the condition of the walls when workmen have to cut openings in them to make alterations. The walls were 14 inches thick and built entirely with unskilled labour—not a bricklayer was employed on the job. H.M. Office of Works does not claim that it costs less to build a house in concrete than brick; the great scarcity of bricklayers, however, demands that if housing schemes are to be completed within a reasonable time the houses must be constructed by some such process as that mentioned above. Although stonemasons hold that the laying of concrete blocks is within their scope, it is usual to employ bricklayers for this purpose. To build houses of concrete blocks does not solve the problem arising out of scarcity of bricklayers; in the shuttering process much of the work can be done by unskilled labour. Ex-Service men out of a job can therefore be employed.

Pisé de Terre (Rammed Earth) Houses.

Where walls cannot be built as quickly or cheaply in brick or stone, pisé de terre serves. For this material to be an economical substitute for brick or stone a suitable material must be available at the site; shuttering and tools of an approved type must be used; the work must be well thought out beforehand so that it can be carried out quickly; lastly, the labour for hand ramming must be cheap or power ramming must be substituted. For building soundly the foundations must be solid; above all, the walls must be protected from damp, above and below, from rain, and from accidental water; effective protection must be provided against attack by rats and other vermin. As regards material, anything which will bind into a footpath which will keep clean in both wet and dry weather will make a good pisé wall. Unfortunately the builders of some of the mud cottages erected within recent years in some parts of England have not always been so fortunate as to select suitable materials. Any material or mixture of materials which has not been proved should be subjected to a pressure test by a competent expert. The great disadvantage of mud walls is that water once let into a wall will almost certainly bring it down. Protection against rain is afforded by using a waterproof solution such as silicate of soda to mix the material, or by spreading a waterproof coat on the external surface; damp-courses are necessary not only at the base of the wall but at the top and under all window sills. As regards cost, in ordinary circumstances in view of the present price of labour no economy would be effected by erecting pisé walls in place of brick unless some efficient mechanical means were used for ramming instead of ordinary hand labour.

Timber-framed Cottages.

Timber-framed cottages are being erected under the housing scheme of the Bradfield Rural District Council. The foundations are brickwork on cement concrete. The walls above the level of the damp-course are made up of timber frames, to the outer side of which felt and weather-boarding are fastened; the inner surface is plastered. The contract price for a pair of three-bedroomed houses, a ground floor of which includes a living-room, parlour, scullery and wash-house, and a barn, together with a well, paths, and fencing, is £1355.

Bermondsey Borough Council v. Heath, Brook, and Sneath.

A case of considerable importance to local public health and housing committees has been decided by Mr. H. T. Waddy, the magistrate at the Tower Bridge police-court. It goes to show that local authorities need have no fear of being unable to recover the cost they incur in making houses reasonably fit for human habitation if the owners fail to comply with the notices served upon them. The Bermondsey Council took proceedings against the owners of property in the borough to recover the expenditure incurred by the council in making the property reasonably fit for human habitation under Section 28 of the Housing and Town Planning Act, 1919, the work having been carried out by the council after the owners had failed to do so within the time specified in the notice served upon them under that section. The defendants were concerned with 550 houses which they owned or managed and kept a small staff of workmen permanently employed in attending to their properties. Even under the pressure of statutory notices (76 intimations of work to be done were served under the Public Health Acts between Jan. 1st and April 23rd, 1920, in addition to some 39 notices later, including 28 under the Housing and Town Planning, &c., Act, 1919) the defendants never had more than 22 men engaged at any given time. The magistrate considered that if the defendants had chosen to obtain the services of further workmen they could have done so, and seeing that the local authority, when they took in hand themselves the work of the five houses which were the subject of the action, completed the whole of the work in 15 or 16 days, the period of 21 days stipulated in the notices as the time within which the work was to be completed was on the whole a reasonable time.

ROUMANIA.

(FROM OUR OWN CORRESPONDENT.)

Insanity in the Balkan States.

RECENT statistics show that the number of registered cases of insanity is steadily increasing year by year in all the Balkan States. This increase is generally supposed to be largely due to the war and to the accumulation of chronic cases dismissed from asylums for want of accommodation. It is pointed out in a report dealing with the subject that the science of eugenics must play a very important rôle in the prophylaxis of insanity, and should be carefully studied. When national eugenics become practical politics, the problem of the prevention of insanity will have been largely solved. A Bulgarian neurologist has proposed the sterilisation of degenerates as a means of checking the increase of insanity and degeneracy. Expression of his views has given rise to considerable discussion; the chief superintendent of the hospitals and asylums stigmatised the method as inhuman and inefficacious. He advocated the segregation of degenerates in special colonies, as practised in Sweden; in this way they are prevented from propagating children, and cannot exercise a bad influence on the community.

Mercuric Oxycyanide Powders Instead of Quinine.

A nurse in Professor J. Lovrich's department of the obstetrical clinic at the University of Budapest recently made the mistake of putting 30 mercuric oxycyanide powders into medicine cases instead of as many quinine powders. At the same time a fever patient in one of the gynæcological wards required a dose of quinine; her nurse took one of these powders from the quinine box and administered it; the unfortunate patient died four days later. Both nurses were placed under arrest.

Infectious Pneumonia in Cattle.

In Poland cases of infectious pneumonia have occurred in cattle, infection coming from the Eastern border. Several cases were observed in the neighbourhood of Vilna, but every precaution was taken; the Hungarian frontier was closed against cattle, and numerous veterinary surgeons were sent thither with strict orders to kill every suspected animal, for if the epidemic entered the country about 80 per cent. of cattle would probably be lost. The last two oriental cattle plagues in Hungary occurred in 1871 and 1882, and both were very disastrous. In Bulgaria an outbreak of this disease was checked early in 1914.

The Spread of Venereal Diseases in Budapest.

An institution has been established by the State police where food, work, and shelter are provided for women coming from the provinces; in this way hundreds have been saved from prostitution. Housing conditions render it impossible to extend the scope of surveillance work at present, but whenever possible women who are found unwilling to earn a wage except by prostitution are liable to punishment and transportation from the capital. The venereal hospitals are crowded; daily reports are furnished, giving the numbers of vacant beds, but the latter are immediately filled. The spread of venereal diseases is shown by the following numbers. During police raids on cafés, cabarets, &c., on Nov. 13th 51 women were arrested, of whom 21 were found to be infected; on the 20th, of 25 women arrested 14 required treatment; on the 21st 37 were arrested, of whom 27 had been ill. The authorities are entirely unable to check the rapid spread of secret prostitution. The building of a large new venereal hospital has long been discussed; the Government has promised financial support, and the city of Budapest has granted free ground for the site, but the present expense of building stands in the way of this much-needed means of dealing with a very serious question.

Protection of Children from Alcoholism.

Dr. Doczy, President of the Budapest Order of Good Templars, referring in a recent address to abortion, premature birth, and infant mortality caused by alcoholism in parents, said that the giving of alcohol to children even in very small doses caused chronic general and organic disturbances. In order to avoid the alcoholisation of infants nurses should be forbidden any alcoholic drinks. Children hereditarily disposed to alcoholism should, if possible, be segregated from their families; homes for the protection of children should make definite provision for the care of the young families of habitual drinkers.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The Yellow Cross.

As the matter has excited interest outside this country, I am sending you further details of the Yellow Cross insurance scheme. The events leading up to its formation were as follows. The problem of the general practitioner had been for some time a matter of much discussion in this country, but through the effects of the legislation of the last few years it became a burning one, since the number of possible private patients for the general practitioner was being constantly cut down. An ever-increasing number of people were made more or less compulsory members of the Krankenkasse, or sickness insurance institute, by law. Whilst formerly only manual labourers, artisans, factory hands, &c., had to become members of these institutes, later on the membership was extended also to people earning higher wages. It was originally intended to provide for medical help and sick pay in case of illness, which generally involved a loss of earnings. By the pressure on other classes of population, paid by the month, to become members of the Krankenkasse, these were taken away from the general practitioner. This was bad for the doctor, but also not satisfactory to the insured person, because our system of sickness insurance does not permit free choice of doctor, but allows the patients to attend only those doctors appointed by the Krankenkasse. During the last two years persons without independent means earning anything up to 96,000 kronen a year, have become entitled to free medical aid, remedies, and sick pay from the Krankenkasse, and many have availed themselves of these facilities. Within the last few months endeavours have been made to form a sickness insurance institute for civil servants, and negotiations are even now going on between the Government and the medical organisations with this object. The latter desire to break the prevailing system of appointed doctors and to introduce the system of free choice in order that the pecuniary advantages of these schemes shall be shared by all doctors. However, a voluntary society, the Yellow Cross, founded two years ago to insure persons of the middle classes against sickness, is now conducted on lines worked out by Hofrat Blaschke, a well-known actuary, and apparently reconciles the needs of the public and the profession more successfully than the State schemes. The professional and business classes are not seriously inconvenienced by an occasional illness of short duration; but an illness involving large expenses, such as an operation, or tuberculosis, is a real menace to them, for the fees of surgeons and the cost of nursing homes and sanatoriums are at present very high. An operation followed by two weeks' treatment in a home may cost up to 12-15,000 kronen, or about 10-25 per cent. of the year's income.

Insurance against Operations and Tuberculosis.

The Yellow Cross has managed to secure the principle of free choice of doctors by adopting the rules laid down in the English National Insurance Act of 1911, which says that any practitioner desiring so may be placed on the list of doctors working under this Act, and that the patient may choose his doctor from amongst the names on the list. The Yellow Cross at present insures its members against only two contingencies—surgical operation of any kind, on the one hand, and tuberculosis, alone among medical conditions, on the other. In case of such an illness the patient chooses his doctor and his sanatorium, arranges as to costs, and he gets his expenses refunded by the Yellow Cross up to the sum insured by him. If, however, the costs are less than the insured amount only the actual costs are refunded; if they amount to more the patient has to find the balance. The unit of insurance is 3000 kronen for any operation, 2500 kronen for tuberculosis; the premium is 6 kronen a month, covering both insurances; 3 kronen a month against an operation only. These premiums are less than half of the ordinary premium paid by members of the Krankenkasse, who get sick pay of 10 kronen a day, but have to rely on the appointed doctor and have to go to a general hospital for operation. The units of 3000 kronen (operation) 2500 (tuberculosis) may be increased up to five times that sum by payment of adequately multiplied premiums. Only such operations are covered by the premiums which cost, according to the minimum fee list of the Vienna Medical Council, at least 600 kronen (so that minor surgery is excluded). A list is issued giving the sum that is payable in the event of any one of the numerous specified operations which are covered by the premium. A number of major operations are given herewith, as examples, together with the sums which are insured by payment of the simple premium.

	Kronen.
Mastoid operation	1300
Enucleation of the eye...	1000
Removal of hæmorrhoids	1300
Appendicectomy	1800
Obstetric operations ...	1200-2000
Cancer of the larynx with removal	3000
Thyroidectomy	2000
Amputation of the mamma	1600

It will be understood that these are only the units and that a doubled or trebled premium will insure for a higher amount in exact proportion. At the present time three units suffice to cover all expenses connected with an appendix, kidney, or mastoid operation in one of our second-class private sanatoriums. As regards tuberculosis, a treble unit will no doubt meet the expenses of a stay in a home for about two months. The insured sum is not to cover all expenses, but to form a substantial help.

The Coöperation of Banks and Businesses.

As regards the possibilities of meeting the financial requirements of the Yellow Cross, actuarial investigations have shown that a membership of at least 10,000 members would be necessary if the association were to rely only on its own income. But by means of re-insurance with the two biggest insurance companies —a private one and an official (State) insurance company —the risks of the association have become almost nil. A special feature is the opportunity for collective insurance by corporations, banks, schools, industrial concerns, &c., of their members against tuberculosis alone or operations alone, if a minimum of 100 persons is insured by them. If a number of annual premiums are paid in advance certain discounts are allowed. The Union of Specialists of Vienna, with a membership of about 550, has joined the Yellow Cross insurance against tuberculosis. Each member pays a yearly premium of 24 kronen to his union, which in its turn arranges payment with the Yellow Cross. The Medical Sickness Club of Vienna has insured its 1200 members against operation. At present the number of persons insured in the Yellow Cross, which has recently changed its name and is in future to be known as "Krankenschutz" (protection against illness), amounts only to 2600, but the membership has increased very considerably during 1920. Up to now sums amounting to 50,000 kronen have been paid out, being equal to about 50 per cent. of the premiums received last year. Taking into consideration the difficulties with which the association had to grapple, since its aims are distinctly opposed to those of the now defunct social-democratic government, it is no wonder that its expansion has not been greater. But the advantages offered by this scheme are now becoming clear.

Within the last few weeks it has been found necessary to take certain precautions when accepting candidates for insurance. Persons applying for insurance against tuberculosis must submit to a medical examination by a doctor appointed by the association, whilst those applying for insurance against an operation have to produce a certificate of health from their regular medical adviser. When corporations join the Yellow Cross collectively certificates or examination of their members are not insisted on. The medical organisations in Vienna have asked their members to point out to their patients the advantages of insurance in the Krankenschutz, and the movement is expected to have important developments.

Dec. 31st, 1920.

URBAN VITAL STATISTICS.

(Week ended Dec. 25th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 13·2, 12·9, and 15·3 in the three preceding weeks, fell to 15·1 per 1000. In London, with a population of nearly 4½ million persons, the death-rate was 15·3, or 0·7 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 6·5 in Darlington, 7·4 in Ipswich, and 8·0 in Enfield, to 23·0 in Southport, 23·9 in Exeter, and 24·2 in Middlesbrough. The principal epidemic diseases caused 216 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 79 from infantile diarrhœa, 64 from diphtheria, 34 from measles, 20 from scarlet fever, 16 from whooping-cough, and 3 from enteric fever. Measles caused a death-rate of 2·8 in Walsall and 2·9 in Middlesbrough. There were 4780 cases of scarlet fever and 2547 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4994 and 2654 respectively at the end of the previous week. The causes of 41 of the 5149 deaths in the 96 towns were uncertified, of which 8 were registered in Birmingham and 3 each in Southend-on-Sea and Barrow-in-Furness.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had been 13·5, 15·2, and 16·1 in the three preceding weeks, further rose to 16·2 per 1000. The 338 deaths in Glasgow corresponded to an annual rate of 15·8 per 1000, and included 7 from whooping-cough, 5 from diphtheria, 4 from scarlet fever, 3 from infantile diarrhœa, and 1 each from enteric fever and small-pox. The 116 deaths in Edinburgh were equal to a rate of 17·7 per 1000, and included 4 from measles and 2 from diphtheria.

Irish Towns.—The 141 deaths in Dublin corresponded to an annual rate of 17·7, or 2·5 per 1000 below that recorded in the previous week, and included 6 from infantile diarrhœa. The 136 deaths in Belfast were equal to a rate of 17·2 per 1000, and included 3 from infantile diarrhœa, 2 from diphtheria, and 1 from scarlet fever.

(Week ended Jan. 1st, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 12·9, 15·3, and 15·1 in the three preceding weeks, rose to 16·6 per 1000. In London, with a population of nearly 4½ million persons, the death-rate was 16·5, or 1·2 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 7·9 in Ilford, 8·1 in Oxford, and 8·3 in East Ham, to 24·8 in Sunderland, 27·1 in Hastings, and 27·7 in Bath. The principal epidemic diseases caused 249 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 96 from infantile diarrhœa, 63 from diphtheria, 34 from measles, 33 from whooping-cough, 17 from scarlet fever, and 6 from enteric fever. Measles caused a death-rate of 1·1 in Newcastle-on-Tyne, 1·3 in Warrington, and 2·5 in Middlesbrough, and whooping-cough of 1·4 in Sunderland. There were 4817 cases of scarlet fever, 2642 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4780, 2547, and 0 respectively at the end of the previous week. The causes of 45 of the 5679 deaths in the 96 towns were uncertified, of which 11 were registered in Birmingham, 6 in Liverpool, 5 in London, and 3 in Gateshead.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had increased from 13·5 to 16·2 in the four preceding weeks, further rose to 18·4 per 1000. The 375 deaths in Glasgow corresponded to an annual rate of 17·6 per 1000, and included 12 from whooping-cough, 5 from infantile diarrhœa, 3 from diphtheria, 2 from small-pox, and 1 from scarlet fever. The 126 deaths in Edinburgh were equal to a rate of 19·3 per 1000, and included 2 from diphtheria, and 1 each from measles, whooping-cough, and infantile diarrhœa.

Irish Towns.—The 214 deaths in Dublin corresponded to an annual rate of 26·9, or 9·2 per 1000 above that recorded in the previous week, and included 2 from infantile diarrhœa, and 1 each from enteric fever, whooping-cough, and diphtheria. The 166 deaths in Belfast were equal to a rate of 21·0 per 1000, and included 2 each from scarlet fever, whooping-cough, and infantile diarrhœa.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lieut. (D) M. F. Hopson to be Surgeon Lieutenant Commander (D).

ROYAL ARMY MEDICAL CORPS.

Major G. W. Heron relinquishes the acting rank of Colonel.

Capt. S. Arnott is restored to the establishment.

Temp. Capt. W. W. Forbes relinquishes the acting rank of Major.

The undermentioned Lieutenants (temporary Captains) to be Captains: D. J. H. Jones, T. H. Twigg, J. K. Holland, K. Masson, and R. S. Strachan.

J. A. B. Sim to be temporary Lieutenant.

Officers relinquishing their commissions:—Temp. Maj. W. A. Brend retains the rank of Major. Temporary Captains retaining the rank of Captain: O. V. Burrows, F. H. Cleveland, J. A. MacSweeny, S. Wigglesworth, and W. Kingdon. Temp. Lieut. D. M. O'Dwyer retains the rank of Lieutenant.

SPECIAL RESERVE OF OFFICERS.

Lieut.-Col. J. H. P. Graham relinquishes his commission and retains the rank of Lieutenant-Colonel.

TERRITORIAL FORCE.

Major M. J. Mahoney resigns his commission and retains the rank of Major.

Capt. G. R. E. G. Mackay resigns his commission and is granted the rank of Major.

Capts. J. Paton and P. J. Watkin (late R.A.M.C.) to be Captains.

Capt. L. R. G. de Granville to be Lieutenant and to relinquish the rank of Captain.

Capts. J. Ramsay and G. B. Gill to be Majors.

Capt. A. E. Richmond to be Adjutant of the R.A.M.C. School of Instruction, West Lancs. Division (T.F.).

H. M. Brown (late Devon Regiment) to be Lieutenant.

Supernumerary for Service with the Officers Training Corps.—Temp. Capt. V. G. L. Fielden resigns his commission and retains the rank of Captain.

TERRITORIAL FORCE RESERVE.

Capt. E. G. Annis resigns his commission and is granted the rank of Major.

ROYAL AIR FORCE.

The undermentioned Flight Lieutenants are granted the honorary rank of Squadron Leader: J. Keenan, J. N. Macdonald, and J. Valerie.

ORDER OF THE BRITISH EMPIRE.

Surg.-Cmdr. T. W. Myles, R.N., has been appointed a Commander of the Civil Division of the Most Excellent Order of the British Empire; and Surg.-Lieut. J. D. Bangay, R.N., an Officer of the Civil Division of the Order.

TERRITORIAL FORCE DECORATION.

The King has conferred the Territorial Force Decoration upon the following officers:—Major J. F. Christie, attached 4th Battalion, Gordon Highlanders; Major A. C. Turner, attached 49th (West Riding) Divisional Engineers; Major E. L. Anderson, 2nd West Lancs. Field Ambulance; Major J. W. Mackenzie, 1st Highland Mounted Brigade Field Ambulance; Major A. H. Horsfall, attached Royal Herbert Hospital, Woolwich; Major J. M. Bowie, attached 9th Battalion, Royal Scots; Lieut.-Col. A. W. Mackintosh, 1st Scottish General Hospital; Lieut.-Col. (Brevet Col.) A. Napier, Honorary Surgeon-Colonel (Honorary Surgeon-Colonel, retired, Volunteers), 4th Scottish General Hospital (retired).

DEATHS IN THE SERVICES.

Lieut.-Col. Richard Henderson Castor (late I.M.S.), at his residence at Croydon, aged 59. He retired from the Service in November, 1920, after 33 years' active work. He served with the Wuntho Expedition in Burma in 1891, was mentioned in despatches and received the medal and clasp. He was an authority on tropical diseases, and established infant welfare work in Burma, in recognition of which he received the Kaisar-i-Hind medal. Col. Castor joined the Ministry of Pensions medical staff, and was appointed to Croydon.

WEYMOUTH HOSPITALS: PROPOSED AMALGAMATION NEGATIVED.—The committees of the Weymouth hospitals have suggested the advantages of the amalgamation of these charities. A public meeting was recently held at Weymouth to consider the matter, the mayor presiding. Eventually the proposition in favour of the amalgamation was defeated. The result of the vote has been conveyed to the joint committee of the hospitals, and it will be for them to decide what further action shall be taken in the matter.

Correspondence.

"Audi alteram partem."

THE BRITISH COMMITTEE FOR AIDING MEN OF LETTERS AND SCIENCE IN RUSSIA.

To the Editor of THE LANCET.

SIR,—We have recently been able to get some direct communication from men of science and men of letters in North Russia. Their condition is one of great privation and limitation. They share in the consequences of the almost complete economic exhaustion of Russia; like most people in that country, they are ill-clad, underfed, and short of such physical necessities as make life tolerable. Nevertheless, a certain amount of scientific research and some literary work still goes on. The Bolsheviks were at first regardless and even in some cases hostile to these intellectual workers, but the Bolshevik Government has apparently come to realise something of the importance of scientific and literary work to the community, and the remnant (for deaths among them have been very numerous) of these people, the flower of the mental life of Russia, has now been gathered together into two special rationing organisations which ensure at least the bare necessities of life for them.

These organisations have their headquarters in two buildings known as the House of Science and the House of Literature and Art. Under the former we note such great names as those of Pavlov, the physiologist and Nobel prizeman; Karpinsky, the geologist; Borodin, the botanist; Belopolsky, the astronomer; Tagantzev, the criminologist; Oldenburg, the orientalist and permanent secretary of the Petrograd Academy of Science, Koni, Bechterev, Latishev, Morozov, and many others familiar to the whole scientific world. Several of these scientific men have been interviewed and affairs discussed with them, particularly as to whether anything could be done to help them. There were many matters in which it would be possible to assist them, but upon one in particular they laid stress. Their thought and work is greatly impeded by the fact that they have seen practically no European books or publications since the Revolution. This is an inconvenience amounting to real intellectual distress. In the hope that this condition may be relieved by an appeal to British scientific workers, Professor Oldenburg formed a small committee and made a comprehensive list of books and publications needed by the intellectual community in Russia if it is to keep alive and abreast of the rest of the world.

It is, of course, necessary to be assured that any aid of this kind provided for literary and scientific men in Russia would reach its destination. The Bolshevik Government in Moscow, the Russian trade delegations in Reval and London, and our own authorities have therefore been consulted, and it would appear that there will be no obstacles to the transmission of this needed material to the House of Science and the House of Literature and Art. It can be got through by special facilities even under present conditions.

Many of the publications named in the Oldenburg list will have to be bought, the costs of transmission will be considerable, and accordingly the undersigned have formed themselves into a small committee for the collection and administration of a fund for the supply of scientific and literary publications, and possibly if the amount subscribed permits of it, of other necessities, to these Russian savants and men of letters. We hope to work in close association with the Royal Society and other leading learned societies in this matter. The British Science Guild has kindly granted the committee permission to use its address.

We appeal for subscriptions and ask that cheques should be made out to the Treasurer, C. Hagberg Wright, LL.D., and sent to the British Committee for Aiding Men of Letters and Science in Russia, British Science Guild Offices, 6, John-street, Adelphi, London, W.C. 2.—We are, Sir, yours faithfully,

ORAL SEPSIS.

To the Editor of THE LANCET.

SIR,—It would be unfair to British medicine, and more especially to the dental section of it, were Dr. W. Bertram Watson's paper on this subject in your last issue to pass unchallenged. His contention that medical men in this country are now learning from America the dangers of oral sepsis and the value of radiography in its diagnosis is grossly unfair. To consider oral sepsis first. The first great stir on the subject was made by Dr. W. Hunter in 1898, and immediately the subject was taken up by dental surgeons and others in this country, as is proved by the steady stream of papers from 1898 on. At the Royal Dental Hospital the gospel of the clean mouth has been taught at least since 1904, when instructions were issued by the hospital authorities that no conservative work should be undertaken until the mouth had been rendered free of sepsis by the removal of septic teeth. At the Great Ormond Street Children's Hospital, to my own knowledge, the radical removal of all septic teeth was instituted in 1902, and a post-graduate lecture on the subject was delivered the same year. In American literature you will find practically no mention of the subject down to 1910 or even later. The earliest reference to the subject in the bibliography attached to Rosenow's paper on Elective Localisation, referred to by Dr. Watson, is 1912. It is quite true that American doctors have recently taken up the subject with a characteristic vigour and thoroughness.

With regard to dental radiography, Rontgen rays were discovered in 1895. In England Mr. A. C. Cossar designed a special dental tube in 1896, and in the same year Mr. C. A. Clark, a dentist, took up the subject and has practised it as a specialty ever since. In 1908 Mr. Clark was appointed radiographer to the X ray department at the Royal Dental Hospital. In the Odontological Society's transactions for April, 1900, there is a paper by Mr. Goldie, of Edinburgh, in which there is a beautiful reproduction of a dental radiogram showing rarefaction of the bone due to periodontal trouble. The fact that increased transradiancy means rarefaction of bone is pointed out and has been the common knowledge of medical radiologists almost since the inception of the science. Had Dr. Watson known of this paper or been familiar with radiographic findings he would not have had to wait until 1919 to learn this very elementary fact at the Mayo clinic.

It is not my intention to criticise the scientific value of Dr. Watson's paper. He admits that his experience in the subject is "small," and were his knowledge of its history larger, he would have realised that it was the doctors in this country rather than the dentists who were so long in grasping the importance of this condition.—I am, Sir, yours faithfully,

London, W., Jan. 3rd, 1921. STANLEY COLYER, M.D.

X RAY TREATMENT OF RINGWORM.

To the Editor of THE LANCET.

SIR,—The letter of Dr. James Neal, Joint Secretary of the Medical Defence Union, is one of great interest to all those who are concerned with the X ray treatment of ringworm, but it would perhaps be as well to point out, as doubtless Dr. Neal knows, that in spite of the violent reaction which at times occurs no ultimate harm results to the child's head of hair, although at the time possibly some slight irritation, readily allayed by soothing applications, is experienced. At the same time I might point out the great importance of after-treatment of children who have been X rayed. In the course of treatment of ringworm of the scalp, in my experience by no means does epilation occur so satisfactorily as is commonly thought; it is the case over again of the old fairy tales, so many of which end "they married and lived happily ever *afterwards*." After X ray treatment for ringworm all the children should be seen at regular intervals in order to ensure that the hair on the rims, which appear to be unavoidably left in some instances, does not contain ringworm, and if it does that the ringworm hair should be epilated. Unfortunately, not only are rims left, but the actual patches of ringworm do not always epilate satisfactorily.

My letter does not in any way militate against the treatment of ringworm of the scalp by X rays. As a result of actual carrying out of the treatment of a considerable number of cases myself, and seeing the children shortly after other workers have X rayed the children's heads, I consider that at least one in ten of the children require constant care and epilation. This view, it would seem, was also held by Dr. R. H. Crowley when medical superintendent for the Bradford Education Committee; many will agree that the application of X rays facilitates epilation, even in these obstinate cases.

I am, Sir, yours faithfully,

Richmond, Surrey, Jan. 1st, 1921. C. W. HUTT.

To the Editor of THE LANCET.

SIR,—Referring to the warning and recommendation of the Medical Defence Union in your issue of this date, it may interest your readers to know that 12 or more years ago I had printed a number of forms, of which I enclose one, with the idea of getting parents of children with ringworm of the head to sign one before undertaking treatment. These forms I copied from one in use in a London hospital. Not once did I succeed in getting any parent to sign and the mere suggestion of danger frightened the parents into a refusal to allow X ray treatment. Our methods were bad in those days, and I had several permanent alopecias to my discredit. In fact, so worried was I over the subject that for five years I absolutely refused to touch ringworm of the scalp with X rays, no matter what fee was offered. The Bradford Education Committee then approached me with a view to treating the Bradford school children. Taking my courage in both hands, I started to work out a technique which I could rely upon and in a few months I succeeded. In the past four years I have treated over 600 cases without a single failure to get the hair out or for it to come in again, and last year I treated 175 cases, and the average time from commencement of treatment to readmission to school was 23 days. Every child treated is inspected by me six months later to see the final results. Every case has the *whole* head epilated by the Kienboch method.

In my opinion no one who has not qualified in the bitter school of experience in all classes of X ray work, and it takes years, ought to attempt the X ray treatment of tinea tonsurans, which is the most exact and exacting form of X ray treatment there is. I do not believe, as Dr. Neal says, that minimum doses ever produce violent dermatitis. Such is produced only by over-dosage and usually by too soft a tube. Personally I work with a small milliampèrage (0·5 ma.) for two reasons: first, because the tube remains more constant, and, secondly, because the margin for error is larger than when using a larger current. I use a light anode tungsten target tube, as I find heavy anode tubes are apt to give out occluded gases and become soft. I always use a filter of 0·2 mm. of aluminium, and I use pastiles for *every* exposure—i.e., five for each case. I also use the Lovibond tintometer as devised by Dr. Dudley Corbett and have found it to be absolutely correct. When working with "Sabouraud and Noiré's pastilles" I give 1 B. dose, but when using "London pastiles" I give 4/5 B., as I find there is 1/5 B. difference between them. It is very important to get accustomed to one class of pastile and to stick to it. There are other tintometers on the market and several are far from reliable. Of one make I purchased two, one for my own private use and one for the Royal Infirmary. Neither was correct, and more astonishing still, there was 100 per cent. difference between the two, although made by the same firm. In conclusion, I should say that I never use a tube emitting rays less than 1 Benoist.

With this technique thoroughly standardised I never have the slightest nervousness as to results. Of course, it is important to watch that the child does not move its head during treatment otherwise an improper overlap might occur. This is best achieved by a watchful nurse, as retentive appliances frighten the children.

I am, Sir, yours faithfully,

Bradford, Jan. 1st, 1921. WILLIAM MITCHELL, M.B.

[ENCLOSURE.]

Bradford Royal Infirmary.

CHILDREN SUFFERING FROM RINGWORM.

I quite understand that there is a very slight risk in carrying out the X ray treatment of Ringworm, namely, that the re-growth of the hair may be incomplete, and I am prepared to take that risk, realising that the hospital authorities are doing their best for my child.

....

THE RADIOGRAPHY OF THE CHEST.

To the Editor of THE LANCET.

SIR,—I should like to remark that the adjective "antiquated" still means "grown old" or "out of fashion." In neither sense can it be applied to the X ray classification adopted in my book on pulmonary tubercle reviewed in THE LANCET, Jan. 1st (p. 29). Obviously it is either a misconception or a misprint. Furthermore, the classification is not difficult to understand provided that the reader is gifted with ordinary application and an average intelligence.

You also find fault with me, because, in the first chapter, when describing the pulmonary reticulum, I have not rested content with the results of Dunham's investigations. Must I assume that you are ignorant of the vast amount of work which has been done to elucidate this problem? Facts and arguments, which, I think, are irrefutable, are given in order to prove that *both vessels and bronchi* must participate in the production of the tracery of the *normal* lung. Concerning the rest of the criticism I have nothing to add.

I am, Sir, yours faithfully,

WALKER OVEREND, M.D., &c.

St. Leonards-on-Sea, Jan. 1st, 1921.

PULMONARY TUBERCULOSIS:

CLASSIFICATION OR SUMMARY (?)

To the Editor of THE LANCET.

SIR,—It is an open secret that the Health Ministry has under consideration the classification of tuberculous cases for administrative purposes, and much informal discussion has taken place, some of it resulting in interesting papers in the journals.[1] There appears to be some confusion in the minds of some who are called upon to deal with tuberculosis statistics. Classification in these cases is required for two distinct reasons—administrative and clinical respectively. In the first case we require the statistics as a guide to the prevalence of such cases in the locality, and to their probable future and needs; in the second as a guide to progress and the effects of treatment.

Much more detail is needed for the second purpose; but all the details are not suitable for use in classification. By far the most convenient method is to employ a simple classification based upon a few outstanding facts and to reserve other details for periodical summaries. If these are put into abbreviated or symbolic form and recorded on a card index comparison at different periods is easy, whereas if we merely record "Much improved" or some similar comparative statement such comparisons are impossible. Four groups of facts may be conveniently symbolised to record progress: systemic disturbance, respiratory disturbance, complications present, and capacity for exercise or work. The first three may be recorded in one of three degrees, the last in hours per day. All these should be subordinate to the anatomical condition, which is more permanent and better suited as a basis for classification.

---

I am, Sir, yours faithfully,

F. R. WALTERS, M.D.,

Tuberculosis Officer to the Surrey County Council.

Farnham, Surrey, Jan. 1st, 1921.

ANNUAL MEETING OF FELLOWS AND MEMBERS AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editor of THE LANCET.

SIR,—On reading over recent issues of your journal I was very much surprised that no account of the above meeting, which was held on Thursday, Nov. 18th, 1920, at 3 P.M., appeared in the issue of Nov. 27th. Since I became a member of the Society of Members—some 18 years ago—I have never failed to read an interesting and fairly full account of the proceedings at the annual meeting at our College in the issue of THE LANCET immediately succeeding that function. Owing to this omission, perhaps you will not object to my informing you that the two resolutions brought forward on behalf of the society were both carried nem. con. We therefore trust that, as last year, they will be sympathetically considered by a committee of the Council specially detailed for the purpose.

In the annual report of the College for 1919–20 it is stated that "the Council have no power under the charters of the College to nominate Members to represent the interests of general practitioners in the management of College affairs," and that after several meetings "it was decided that it was not desirable to apply for a new charter for the purpose." At the above-mentioned annual meeting the representatives of the Society of Members entered an emphatic protest against the first of these statements, as we believe that the Council have such power at the present time, but are (as a whole) unwilling to exercise it. As regards the second statement, history records that the Council have had no compunction in applying for charters in order to obtain increased powers for themselves or to deprive the Members of nearly all their ancient privileges. Their diffidence in this case is really due to the knowledge that an application for a charter will provide an excellent opportunity for the Society to defend and enlarge the position of the Members, of which we shall take full advantage.

I am, Sir, yours faithfully,

SIDNEY C. LAWRENCE,

Hon. Secretary, Society of Members of the Royal College of Surgeons of England.

61, Wellington-road, Bush Hill Park, Enfield, Jan. 2nd, 1921.

DONATIONS AND BEQUESTS.—A contribution of £7000 has been received by the Royal Portsmouth Hospital from the Prince of Wales's National Relief Fund. This amount represents the deficit incurred during the four years of war. Only the deficit for 1920 remains to be made good in order to render the institution free from debt.—The Ashton District Infirmary has received a gift of £6300 from the Prince of Wales's Fund.—The board of management of the Manchester Royal Infirmary have received during the past month legacies and donations amounting to £6052.—The employees of Messrs. A. Hall and Co., Ltd., shipbuilders, Aberdeen, contributed on behalf of the Hospital Fund during the past year the sum of £41 16*s*. The firm gave a like amount, making a total of £83 12*s*. The following allocations were made: Aberdeen Royal Infirmary, £50; Aberdeen District Nursing Association, £4 10*s*.; Aberdeen Eye Institution, £7 10*s*.; Royal Aberdeen Hospital for Sick Children, £20; Aberdeen Asylum for the Blind, £1 12*s*.—The annual parish of Keith-hall collection for the Aberdeen Infirmary for 1920 amounted to £30 18*s*. 6*d*.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Six Hunterian lectures on the Principles of Human Craniology, illustrated by specimens and preparations, will be delivered in the theatre of the College in Lincoln's Inn-fields by Professor Arthur Keith in the last fortnight in January. The lectures will be given at 5 P.M. on Mondays, Wednesdays, and Fridays, beginning on Jan. 17th. The syllabus is as follows: I. The beginnings of craniology; its aims; the skull considered from a functional point of view; the cranial cavity, its growth and shape; cranial form as a mark of race. II. The manner in which the occipital and mastoid regions become modified in passing from infancy to old age; changes due to disordered growth; the base of the skull and the manner in which the face is hafted to it. III. The purposes served by the various bones of the face; the mechanism of facial growth; prognathism; the face as a mark of race. IV. The significance of certain modifications effected in the skull under various conditions of disordered growth (acromegaly, achondroplasia, osteogenesis imperfecta, cretinism, &c.). V. Conditions which regulate the shape of the skull as illustrated by anomalous crania (scaphocephaly, acrocephaly, microcephaly, hydrocephaly, and other less common abnormal states). VI. The nature of the changes which are taking place in the skulls of peoples living under modern conditions of life.

UNIVERSITY OF LONDON.—At the last meeting of the Senate it was decided to institute a University Chair of Anatomy tenable at St. Bartholomew's Hospital Medical School. At the same meeting it was also decided that a candidate for the Diploma in Psychological Medicine who has passed the examination for M.D. in Branch III., Mental Diseases and Psychology, be exempted from examination in psychology and psychological medicine, and be awarded the Diploma in Psychological Medicine on satisfying the examiners for the Diploma in Part A (i.), Anatomy, Histology, and Physiology of the Nervous System, and Part B (i.), Neurology.

The Council of the Royal College of Surgeons of England has appointed Mr. Frederic F. Burghard to be its representative on the Senate in the place of Sir Charles Ballance, who has resigned. Dr. F. Ransom (London (R.F.H.) School of Medicine for Women) has been appointed professor of pharmacology in the University of London.

Studentships and Scholarships: The Senate invites applications for the Graham Scholarship in Pathology of the value of £400 per annum for two years, founded under the will of the late Dr. Charles Graham to enable a young man to continue his pathological researches and at the same time to secure his services to the school of advanced medical studies connected with University College Hospital as a teacher under the direction of the professor of pathology. Intending applicants who desire fuller information of the conditions on which the scholarship will be held may call personally on the professor of pathology, University College Hospital Medical School, London, W.C. 1.

Lectures: Under the scheme for the exchange of lecturers between Holland and England the University has invited the undermentioned Dutch lecturers to give one lecture each on a medical subject, in English, during the present session: Dr. W. Einthoven, professor of physiology, Leyden; Dr. C. M. Ariens Kappers, director of "Herseninstituut," Amsterdam; Dr. J. K. A. Wertheim Salomonson, professor of neurology, Amsterdam; Dr. Bolk, professor of anatomy, Amsterdam; Dr. J. Boeke, professor of embryology and histology, Utrecht; Dr. Hamburger, professor of physiology, Groningen. The first lecture, entitled "Some Considerations on Tonus and Reflexes," will be delivered by Dr. Wertheim Salomonson at the rooms of the Royal Society of Medicine on Monday, Jan. 17th, at 5 P.M., when the chair will be taken by the Vice-Chancellor.

A course of eight lectures on the Physiology of the Embryo, Fœtus, and Newly-born will be given at Guy's Hospital by Dr. M. S. Pembrey, professor of physiology in the University, on Thursdays at 4.30 P.M., beginning on Jan. 13th. The lectures are addressed to advanced students and to others interested in the subject, and are recognised as advanced lectures which a candidate at the B.Sc. Honours Examination may name for part of his examination. Admission is free for all these lectures without ticket.

On Feb. 3rd, 10th, and 17th, at 5.30 P.M., at University College, Gower-street, Professor J. E. G. de Montmorency, LL.B., will lecture on Mother-right and Matriarchy.

In the Psychological Department, King's College, Strand, Dr. William Brown will give a course of ten lectures on Psychopathology on Tuesdays, at 5.30 P.M., beginning on Tuesday, Jan. 18th. These lectures are open to medical students and medical practitioners without fee or ticket.

point out the great importance of after-treatment of children who have been X rayed. In the course of treatment of ringworm of the scalp, in my experience by no means does epilation occur so satisfactorily as is commonly thought; it is the case over again of the old fairy tales, so many of which end "they married and lived happily ever afterwards." After X ray treatment for ringworm all the children should be seen at regular intervals in order to ensure that the hair on the rims, which appear to be unavoidably left in some instances, does not contain ringworm, and if it does that the ringworm hair should be epilated. Unfortunately, not only are rims left, but the actual patches of ringworm do not always epilate satisfactorily.

My letter does not in any way militate against the treatment of ringworm of the scalp by X rays. As a result of actual carrying out of the treatment of a considerable number of cases myself, and seeing the children shortly after other workers have X rayed the children's heads, I consider that at least one in ten of the children require constant care and epilation. This view, it would seem, was also held by Dr. R. H. Crowley when medical superintendent for the Bradford Education Committee; many will agree that the application of X rays facilitates epilation, even in these obstinate cases.

I am, Sir, yours faithfully,
C. W. HUTT.

Richmond, Surrey, Jan. 1st, 1921.

To the Editor of THE LANCET.

SIR,—Referring to the warning and recommendation of the Medical Defence Union in your issue of this date, it may interest your readers to know that 12 or more years ago I had printed a number of forms, of which I enclose one, with the idea of getting parents of children with ringworm of the head to sign one before undertaking treatment. These forms I copied from one in use in a London hospital. Not once did I succeed in getting any parent to sign and the mere suggestion of danger frightened the parents into a refusal to allow X ray treatment. Our methods were bad in those days, and I had several permanent alopecias to my discredit. In fact, so worried was I over the subject that for five years I absolutely refused to touch ringworm of the scalp with X rays, no matter what fee was offered. The Bradford Education Committee then approached me with a view to treating the Bradford school children. Taking my courage in both hands, I started to work out a technique which I could rely upon and in a few months I succeeded. In the past four years I have treated over 600 cases without a single failure to get the hair out or for it to come in again, and last year I treated 175 cases, and the average time from commencement of treatment to readmission to school was 23 days. Every child treated is inspected by me six months later to see the final results. Every case has the *whole* head epilated by the Kienboch method.

In my opinion no one who has not qualified in the bitter school of experience in all classes of X ray work, and it takes years, ought to attempt the X ray treatment of tinea tonsurans, which is the most [illegible] and exacting form of X ray treatment there is. I do not believe, as Dr. Neal says, that minimum doses ever produce violent dermatitis. Such is produced only by overdosage and usually by too soft a tube. Personally I work with a small milliamperage (0·5 ma.) for two reasons: first, because the tube remains more constant, and, secondly, because the margin for error is larger than when using a larger current. I use a light anode tungsten target tube, as I find heavy anode tubes are apt to give out occluded gases and become soft. I always use a filter of 0·2 mm. of aluminium, and I use pastilles for *every* exposure—i.e., five for each case. I also use the Lovibond tintometer as devised by Dr. DeRoy Corbett and have found it to be absolutely correct. When working with "Sabouraud and Noiré's pastilles" I give 1 B. dose, but when using "London pastilles" I give 4·5 B., as I find there is 3·5 B. difference between them. It is very important to get accustomed to one class of pastille and to stick to it. There are other tintometers on the market and several are far from reliable. Of one make I purchased two, one for my own private use and one for the Royal Infirmary. Neither was correct, and more astonishing still, there was 100 per cent. difference between the two, although made by the same firm. In conclusion, I should say that I never use a tube emitting rays less than 1 Benoist.

With this technique thoroughly standardised I never have the slightest nervousness as to results. Of course, it is important to watch that the child does not move its head during treatment otherwise an improper overlap might occur. This is best achieved by a watchful nurse, as retentive appliances frighten the children.

I am, Sir, yours faithfully,
WILLIAM MITCHELL, M.B.

Bradford, Jan. 1st, 1921.

[ENCLOSURE.]

Bradford Royal Infirmary.

CHILDREN SUFFERING FROM RINGWORM.

I quite understand that there is a very slight risk in carrying out the X ray treatment of Ringworm, namely, that the re-growth of the hair may be incomplete, and I am prepared to take that risk, realising that the hospital authorities are doing their best for my child.

....

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Six Hunterian lectures on the Principles of Human Craniology, illustrated by specimens and preparations, will be delivered in the theatre of the College in Lincoln's Inn-fields by Professor Arthur Keith in the last fortnight in January. The lectures will be given at 5 P.M. on Mondays, Wednesdays, and Fridays, *beginning on Jan. 17th*. The syllabus is as follows: I. The beginnings of craniology; its aims; the skull considered from a functional point of view; the cranial cavity, its growth and shape; cranial form as a mark of race. II. The manner in which the occipital and mastoid regions become modified in passing from infancy to old age; changes due to disordered growth; the base of the skull and the manner in which the face is hafted to it. III. The purposes served by the various bones of the face; the mechanism of facial growth; prognathism; the face as a mark of race. IV. The significance of certain modifications effected in the skull under various conditions of disordered growth (acromegaly, achondroplasia, osteogenesis imperfecta, cretinism, &c.). V. Conditions which regulate the shape of the skull as illustrated by anomalous crania (scaphocephaly, acrocephaly, microcephaly, hydrocephaly, and other less common abnormal states). VI. The nature of the changes which are taking place in the skulls of peoples living under modern conditions of life.

UNIVERSITY OF LONDON.—At the last meeting of the Senate it was decided to institute a University Chair of Anatomy tenable at St. Bartholomew's Hospital Medical School. At the same meeting it was also decided that a candidate for the Diploma in Psychological Medicine who has passed the examination for M.D. in Branch III., Mental Diseases and Psychology, be exempted from examination in psychology and psychological medicine, and be awarded the Diploma in Psychological Medicine on satisfying the examiners for the Diploma in Part A (i.), Anatomy, Histology, and Physiology of the Nervous System, and Part B (i.), Neurology.

The Council of the Royal College of Surgeons of England has appointed Mr. Frederic F. Burghard to be its representative on the Senate in the place of Sir Charles Ballance, who has resigned. Dr. F. Ransom (London (R.F.H.) School of Medicine for Women) has been appointed professor of pharmacology in the University of London.

Studentships and Scholarships: The Senate invites applications for the Graham Scholarship in Pathology of the value of £400 per annum for two years, founded under the will of the late Dr. Charles Graham to enable a young man to continue his pathological researches and at the same time to secure his services to the school of advanced medical studies connected with University College Hospital as a teacher under the direction of the professor of pathology. Intending applicants who desire fuller information of the conditions on which the scholarship will be held may call personally on the professor of pathology, University College Hospital Medical School, London, W.C.1.

Lectures: Under the scheme for the exchange of lecturers between Holland and England the University has invited the undermentioned Dutch lecturers to give one lecture each on a medical subject, in English, during the present session: Dr. W. Einthoven, professor of physiology, Leyden; Dr. C. M. Ariens Kappers, director of "Herseninstituut," Amsterdam; Dr. J. K. A. Wertheim Salomonson, professor of neurology, Amsterdam; Dr. Bolk, professor of anatomy, Amsterdam; Dr. J. Boeke, professor of embryology and histology, Utrecht; Dr. Hamburger, professor of physiology, Groningen. The first lecture, entitled "Some Considerations on Tonus and Reflexes," will be delivered by Dr. Wertheim Salomonson at the rooms of the Royal Society of Medicine on Monday, Jan. 17th, at 5 P.M., when the chair will be taken by the Vice-Chancellor.

A course of eight lectures on the Physiology of the Embryo, Fœtus, and Newly-born will be given at Guy's Hospital by Dr. M. S. Pembrey, professor of physiology in the University, on Thursdays at 4.30 P.M., beginning on Jan. 13th. The lectures are addressed to advanced students and to others interested in the subject, and are recognised as advanced lectures which a candidate at the B.Sc. Honours Examination may name for part of his examination. Admission is free for all these lectures without ticket.

On Feb. 3rd, 10th, and 17th, at 5.30 P.M., at University College, Gower-street, Professor J. E. G. de Montmorency, LL.B., will lecture on Mother-right and Matriarchy.

In the Psychological Department, King's College, Strand, Dr. William Brown will give a course of ten lectures on Psychopathology on Tuesdays, at 5.30 P.M., beginning on Tuesday, Jan. 18th. These lectures are open to medical students and medical practitioners without fee or ticket.

Royal Society of Arts.—The Aldred lecture will be delivered by Dr. C. S. Myers, F.R.S., on Wednesday, Jan. 12th, at 8 P.M., on Industrial Fatigue, at the House of the Society, John-street, Adelphi, W.C.

Colonial Medical Service.—Sir James Kingston Fowler will deliver an address entitled "The Colonial Medical Service" at the Middlesex Hospital Medical School on Thursday, Jan. 20th, at 3 P.M., when the Earl of Athlone will preside.

Society for the Study of Inebriety.—The next meeting of the society will be held in the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Tuesday, Jan. 11th, at 4 P.M., when Dr. H. M. Vernon will open a discussion on Alcohol and Industrial Efficiency. Each member and associate is at liberty to introduce visitors.

Harveian Society of London.—The annual general meeting will be held on Thursday, Jan. 13th, at the rooms of the Medical Society of London, 11, Chandos-street, W. The Presidential Address will be delivered by Dr. William Hill on the Great Advances in the Investigation and Treatment of Diseases of the Œsophagus during the Present Century.

West London Medico-Chirurgical Society.—A special general meeting will take place in the society's rooms at the West London Hospital on Friday, Jan. 14th, at 8.30 P.M., in order to discuss the Interim Report on the future provision of medical and allied services recently drawn up for the Ministry of Health. Medical practitioners are cordially invited to attend and take part in the discussion.

Tiverton Hospital and Paying Patients.—At a meeting of the subscribers of the Tiverton (Devon) Hospital held last week it was decided to alter the rules to enable a charge to be made to in-patients.

Irish Hospital Grants.—The Chief Secretary for Ireland has appointed the following committee to advise on the distribution of the portion applicable to Ireland of the National Relief Fund grant towards the war deficits of voluntary hospitals: The Master of the Rolls in Ireland (chairman); Sir Edward Coey Bigger, Mr. Stephen Grehan, Sir James Johnston, Mr. T. B. Lillis, Sir Henry McLaughlin, Mrs. McMordie, and Mr. Laurence Waldron.

Royal Medical Benevolent Fund Guild.—A serious effort is being made to raise more money to help in educating the children of medical men who have died or lost their health before they have been able to make adequate provision for their dependents. The matinée held at His Majesty's Theatre and a dance held on Dec. 23rd last at a house in Wimpole street were both very successful. The owner of this house generously bore all the expenses, including the band and refreshments. Tickets at a guinea each were all sold very quickly. Other doctors who possess suitable houses either in London or in the provincial towns are asked to make a similar effort and thus give their patients an opportunity of materially assisting this charity. Anybody who is willing to lend his house for the purpose of a dance is invited to communicate with the secretary of the Guild at 19, Portland-place, London, W. 1.

National Association for the Prevention of Infant Mortality.—A course of advanced lectures on Infant Care, for infant welfare workers, teachers, mothers, &c., will be held at Morley Hall, George-street, Hanover-square, London, W., on Mondays, at 6 P.M., from Jan. 17th to April 11th. The lecturers include: Mr. Eardley Holland, Mr. Gordon Ley, Dr. Flora Shepherd, Dr. Eric Pritchard, Dr. H. C. Cameron, Mr. M. S. Mayou, Mr. Philip Franklin, Mr. C. F. Peyton Baly, Dr. S. Roodhouse Gloyne, Dr. J. Lawson Dick, Dr. Maurice Craig, and Dr. Harold Waller. Fee for the whole course of 12 lectures, 7s. 6d.; for one lecture, 1s.—A special course of lectures on Infantile Care for health visitors, nurses, midwives, school teachers, voluntary infant welfare workers, committees of nursing associations, &c., will be held in the Lecture Theatre of the Victoria Institute, Worcester, by kind permission of the Higher Education Subcommittee, on Saturday afternoons, from Feb. 12th to March 12th inclusive. Lectures will be given each day, from 2 to 3 P.M., and from 4 to 5 P.M.—Under the joint auspices of this association and the National Society of Day Nurseries a course of elementary lectures on Infant Care, especially intended for creche nurses and probationers, will be held at the Essex Hall, Essex-street, Strand, London, W.C., on Thursdays, at 7.30 P.M., from Jan. 20th to April 14th. The lecture fee for each of these two courses is 10s. each person for the course and 1s. 6d. for a single lecture. Tickets should be obtained in advance from Miss Halford, secretary, National Association for the Prevention of Infant Mortality, 4 and 5, Tavistock-square, London, W.C. 1.

The Fellowship of Medicine and Post-Graduate Medical Association.—At a general Council meeting held on Dec. 10th, 1920, the following resolutions were adopted and referred to the newly-appointed executive committee:—

1. That the executive committee be requested to consider the advisability and practicability of appointing a general organiser of post-graduate medicine, with full powers to take such action as he thinks fit in order to promote the facilities for post-graduate education in the United Kingdom for practitioners registered in this country and for visitors from Dominions and foreign countries. And that the Government be approached with a view to obtaining an annual grant.

2. That the executive committee be requested to report at an early date upon the possibility of providing a hospital solely for post-graduate study and the possibility of obtaining a grant in aid.

3. That it is desirable to obtain as early as possible suitable accommodation for post-graduates attending courses of instruction.

The first meeting of the executive committee will be held at 1, Wimpole-street, London, W., on Tuesday, Jan. 11th. at 5.30 P.M.

Medical Society of London.—The syllabus of the second half of the 148th session has just been issued. On Monday, Jan. 10th, at 8.30 P.M., a pathological evening will be held; specimens and demonstrations by Dr. B. H. Spilsbury, Dr. E. H. Kettle, Dr. E. H. Shaw, Dr. Carnegie Dickson, Dr. A. Fleming, Dr. John Matthews, Dr. Robert Knox. Dr. Crofton Atkins, Dr. Harrison Orton, and Mr. C. A. Clark, M.R.C.S., L.D.S. On Jan. 24th, at 8.30 P.M., a paper on Multiple Neuritis. will be read by Dr. Anthony Feiling, followed by one on Handprints in Mongolian and other Imbeciles by Dr. F. J. Crookshank. On Feb. 14th a discussion on Skin Disease, its relation to Internal Disorder, will be opened by Sir James Galloway, and on Feb. 28th a discussion on the Chemical Estimation of Gastric Function will be introduced by Dr. J. H. Ryffel. On March 14th Sir Henry Gauvain will speak on Non-operative Treatment of Surgical Tuberculosis. The Lettsomian lectures on Surgery of the Lung and Pleura will be delivered on Mondays, Feb. 7th and 21st, and March 7th, at 9 P.M., by Mr. George E. Gask. The annual dinner will be held at the Wharncliffe Rooms, Hotel Great Central, on Tuesday, March 8th, at 7 P.M. for 7.30 P.M. The annual oration will be delivered on May 23rd by Lord Dawson of Penn.

Birmingham Medical Psychological Society.—This society has recently been formed with a membership limited to medical men. The subscription is 5s. per annum, and meetings are held monthly on Wednesdays at 4.15 P.M. The next meeting will take place on Jan. 12th, when Dr. G. J. Branson will read a paper on the Neurotic State. Subsequent meetings will be notified in our Medical Diary. The officers for the session are Dr. A. W. Moore (President); Dr. H. E. McCready (Vice-President); Dr. E. Gordon Anderson (Treasurer). The secretary is Dr. Ernest W. Jones, The Manor House, Aldridge, from whom further information may be obtained.

Birmingham Children's Hospital.—The authorities of the Children's Hospital are about to make an important innovation to meet the needs of those patients, who, whilst above the so-called hospital class, are yet unable to meet the expenses of private nursing homes and operation fees. The new hospital, erected as a memorial to King Edward VII., has 100 empty beds which cannot be used owing to the financial condition of the institution. As a beginning it is proposed to set apart a private ward of six cots for paying patients. The hospital will make a charge of £3 3s. per week, which represents the actual cost to the hospital of food, drugs, and dressings. In addition there will be a fee for medical or surgical treatment, the amount of which will be a matter of arrangement between a member of the staff and the patient's friends. But it is stipulated that this fee shall not exceed a maximum of £3 3s. per week, or, as an alternative, that £21 shall be an inclusive fee, however long the patient may stay in the hospital. For some time the advisability of making a maintenance charge for all patients has been discussed and opinion has been divided on the principle involved. It was felt that it would be more satisfactory if contributions from patients generally could be avoided. Many special hospitals have arranged for payments by patients, but children's hospitals with one or two exceptions have considered the proposal impracticable. Another aspect of the subject has reference to the number of patients drawn from outside districts; of 100 children treated, 78 resided in Birmingham and 22 in other districts. The committee of the hospital has intimated to the local authorities its willingness to negotiate with public health departments with a view to the resources of the hospital and its out-patient department being made available for infant welfare schemes. Whilst most anxious to meet the demand for extra beds, the committee points out that the income of the hospital does not meet the expenditure by some £5000 a year, and therefore this work for local authorities can in future be done only at their expense.

MEDICAL OFFICERS OF HEALTH AND WAR BONUS.—At the last meeting of the Radstock (Somerset) urban district council it was reported that Dr. J. E. Scales, the medical officer of health, and Mr. G. Pearson, the clerk, had resigned their appointments in consequence of the refusal of the council to grant them a war bonus, as recommended in the latest circular of the Ministry of Health.

HOSPITAL CONDITIONS IN MANCHESTER DISTRICT.—The Salford Royal Hospital will probably be faced with a deficit of £10,000, which represents the post-war increase in the cost of running the hospital. The Manchester Children's Hospital at Pendlebury has a deficit of £11,993 on its income and expenditure for 1919, and its bank overdraft stands at £16,500. Already one ward of 30 beds has been closed, and if generous help is not forthcoming immediately more beds must remain unoccupied, in spite of the large waiting list of cases.

PAYING PATIENTS IN POOR-LAW HOSPITALS.—The Manchester board of guardians have decided to provide, from Feb. 1st, limited accommodation—about 200 beds—at their hospitals at Nell Lane, Withington, and Crumpsal, at a charge of 3 guineas weekly inclusive. This charge, it is believed, will cover the cost of the maintenance and treatment of patients. The scheme proposes to utilise the vacant accommodation for patients who cannot be treated at once in the overcrowded voluntary hospitals or who are unable to pay the high fees charged in private nursing homes, and the fees of consulting physicians and surgeons for attendance. It is expected that most of the patients will be emergency surgical cases requiring immediate treatment, the conditions and treatment being the same as in a private hospital. There is a staff of visiting specialists, physicians and surgeons, as well as a visiting gynæcologist, aurist, laryngologist, radiologist, and ophthalmic surgeon.

BRISTOL ROYAL INFIRMARY.—The chairman of the Bristol Royal Infirmary committee, Alderman Frank Sheppard, recently addressed a meeting representative of the employees of the principal firms of the city and appealed for increased support for the infirmary. There is an adverse balance of over £50,000, and expenditure is so largely in excess of income that the committee is faced by the prospect of having to close a number of beds. It is possible that this may be in some measure averted by the Ministry of Pensions, which has offered to use a certain number of beds. Plans for the collection of payments by patients are also under consideration.

ANNUAL RETURNS OF MATERNITY AND INFANTS' HOMES.—In May, 1920, the Minister of Health asked for certain information to be furnished annually to him by the authorities of maternity homes and hospitals on the one hand, and of infants' and children's homes and hospitals on the other. The period then contemplated ended with March 31st, but as the information can be more readily supplied for the calendar than for the financial year, the particuars are in future to be given for the year ending Dec. 31st. It will be remembered that *immediate* information is asked for in regard to every case of maternal mortality occurring in an institution or due to illness contracted there, every case of notified puerperal fever, and every death from gastro-enteritis or epidemic diarrhœa in an infants' hospital.

TREATMENT OF VENEREAL DISEASE IN DUNDEE.—There were 11 applicants for the post, to which Dr. A. C. Profeit was appointed, of medical officer under Dundee's scheme for the treatment of venereal disease. Dr. Profeit, who is an M.D. and D.P.H. of Aberdeen University, is at present in private practice in Ballater, Aberdeenshire, where he holds the post of medical officer of health. From 1900 to 1903 he was in charge of the venereal wards at the Royal Victoria Hospital, Netley, and for several months in 1904 he was in charge of wards in the military hospital at Shorncliffe.

ABERDEEN ORTHOPÆDIC CENTRE.—At a meeting of the Aberdeen Rotary Club held on Dec. 30th, 1920, Dr. Middleton Connon gave an account of the work being done under the auspices of the Ministry of Pensions at the Aberdeen Orthopædic Clinic and Limb-Fitting Centre. Aberdeen was the first city in the British Isles to have an out-patient orthopædic centre. There are now in Scotland four similar centres with a number of subsidiary ones. Aberdeen is the centre for the northern area, said Dr. Connon, which includes all the counties and islands north of and including Kincardineshire, to the Orkneys and Shetlands. The staff includes two assistant medical officers, 26 masseuses, one plaster worker, one qualified surgical nurse, and four clerks. There are at present 623 men under treatment. In the area served there were 670 limbless men. All the eight men in the limb-fitting shop are discharged disabled men wearing artificial limbs.

DIPLOMA OF PSYCHOLOGICAL MEDICINE.—Should sufficient applicants be forthcoming, a third course of lectures and demonstrations for Part I. of the Diploma will be held at the Maudsley Hospital, beginning in April. Intending applicants should communicate at once with the director, Pathological Laboratory, Maudsley Hospital, Denmark Hill, London, S.E. 5.

LITERARY INTELLIGENCE.—The Oxford Medical Publications announce the early publication of a new issue (Vol. I. of the Fourth Series) of Guy's Hospital Reports, under the general editorship of Dr. Arthur F. Hurst, assisted by an editorial committee. The first number will contain articles by Sir W. Hale-White, Dr. G. Newton Pitt, Dr. Hurst, Dr. J. A. Ryle, Mr. R. P. Rowlands, Mr. W. M. Mollinson, and others.—The new edition of the "Literary Year Book" for 1921 will be issued on Jan. 10th by its new proprietor and editor, Mr. Mark Meredith, from the "Year Book" Offices, 67, Dale-street, Liverpool.

Obituary.

THOMAS H. LIVINGSTONE, M.D., F.R.C.S. EDIN.,

HONORARY SURGEON, THROAT, NOSE, AND EAR HOSPITAL, NEWCASTLE-UPON-TYNE.

THE death occurred on Dec. 25th, 1920, in Newcastle-upon-Tyne, of Dr. Thomas Hillhouse Livingstone. He was the younger son of the late Dr. Thomas Livingstone, of Stanhope, in Weardale, who was for over 30 years in practice in Stanhope and who occupied a very prominent position in the public and social life of the dale. Dr. T. H. Livingstone was educated at Wolsingham Grammar School and Uppingham, and proceeded to Edinburgh University, where he graduated M.B., Ch.B., in 1899. He filled the post of house surgeon at Rochdale Infirmary and later carried on his father's practice at Stanhope with much acceptance till 1903. He then returned to Edinburgh for a period and took the M.D. and F.R.C.S. degrees, afterwards settling in practice in Newcastle. He became honorary surgeon to the Hospital for Sick Children and retired from this position in 1912, when he was appointed surgeon to the Throat, Nose, and Ear Hospital. During later years he confined his work entirely to this special branch, to which he had always had a leaning, and in it he had the satisfaction of being able to do much good work. He held a commission in the Territorial Force, and was mobilised at the outbreak of the war. When under orders to proceed to France he was taken seriously ill and was admitted to the 1st Northern General Hospital with the malady which eventually proved fatal. Partially recovering from this illness, he was attached to the ear and throat department of the 1st Northern General Hospital. In 1914 he was made Vice-President of the Ear, Nose, and Throat Section at the annual meeting of the British Medical Association.

By nature Dr. Livingstone was of a most refined and gentle disposition, possessed in a marked degree of innate courtesy and kindness to others. He was much attached to his native dale, and occasional visits from busy Newcastle to his old quiet home in the country always gave him the greatest pleasure. To his many friends both in Weardale and Newcastle his death at the early age of 43 has come as a great grief. His remains were interred in the old churchyard of Stanhope.

THE LATE DR. ROBERT SLATER MAIR.—Dr. Mair, who died on Dec. 21st, 1920, at the ripe age of 95, was a well-known medical practitioner in Bayswater, physician to the Persian Embassy, and for many years certifying factory surgeon for the City of London. Educated at Edinburgh and Glasgow, he graduated at St. Andrews in 1850 and almost immediately went to India, where for 17 years he practised in Madras, for which city he was also deputy coroner. Dr. Mair, who became a Fellow of the Royal College of Surgeons, Edinburgh, in 1863, was the author of a medical guide for Anglo-Europeans, which was published in 1873, and a book on the management of children in India, published two years later.

LIBRARY,
JAIPUR.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Jan. 11th.

SECTION OF PSYCHIATRY: at 8.30 P.M.

Paper:

Dr. Meroweka: The Morbid Conditions of the Choroid Plexus in Mental Disease (illustrated by epidiascope).

Thursday, Jan. 13th.

SECTION OF NEUROLOGY: at 8.30 P.M.

Informal Meeting for free discussion (tea, coffee, smoking).

N.B.—As this is the first of these evenings it is hoped that Members will endeavour to attend and, if possible, exhibit objects of interest.

Friday, Jan. 14th.

CLINICAL SECTION: at 5.30 P.M. (Cases at 5 P.M.)

Cases: The following will be shown by—

Mr. W. E. Tanner: Case of Osteochondritis Deformans.

Mr. W. H. Ogilvie and Mr. Massie: Two Cases of Fracture-Dislocation of the Ankle.

Mr. [illegible]: Impacted Fracture—Separation of Lower Epiphysis of the Femur.

Other cases will be shown.

SECTION OF OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)

Cases and Exhibits:

Mr. G. Winfield Roll: Foreign Body Retained in the Eye for Many Years.

Mr. B. T. Lang: A New Scotometer.

Papers:

Dr. Ransom Pickard: Variations in the Size of the Physiological Cup, and their Relation to Glaucoma.

Mr. B. T. Lang: Scotometry.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Jan. 10th.—8.30 P.M., Pathological Evening. Specimens and Demonstrations by Dr. B. H. Spilsbury, Dr. E. H. Kettle, Dr. E. H. Shaw, Dr. C. Dickson, Dr. A. Fleming, Dr. J. Matthews, Dr. R. Knox, Dr. C. Atkins, Dr. H. Orton, and Mr. C. A. Clark.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

WEDNESDAY, Jan. 12th.—8 P.M., Aldred Lecture:—Dr. C. S. Myers: Industrial Fatigue.

HARVEIAN SOCIETY OF LONDON, at the Medical Society's Rooms, 11, Chandos-street, Cavendish-square, W.

THURSDAY, Jan. 13th.—Annual General Meeting. Presidential Address:—Dr. W. Hill: The Great Advances in the Investigation and Treatment of Diseases of the Œsophagus during the Present Century. General Conversazione.

BIRMINGHAM MEDICAL PSYCHOLOGICAL SOCIETY.

WEDNESDAY, Jan. 12th.—4.15 P.M., Dr. G. J. Branson: The Neurotic State.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Jan. 10th.—12.15 P.M., Dr. Burnford: Pathological Demonstration. 2 P.M., Mr. B. Harman: Eye Department. Dr. Morton: X Ray Department. 5 P.M., Lecture:—Dr. A. Saunders: The Clinical Investigation of Cases with Symptoms of Digestive Trouble.

TUESDAY.—12 noon, Mr. T. Gray: Demonstration of Fractures. 2.30 P.M., Mr. Baldwin: Operations. Mr. Addison: Visit to Surgical Wards. 5 P.M., Clinical Lecture I.:—Mr. Banks Davis.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Gibb: Eye Department. 5 P.M., Lecture I.:—Dr. Simson: Obstetric Emergencies.

THURSDAY.—2 P.M., Dr. G. Stewart: Medical Out-patients. Mr. D. Armour: Operations. Mr. Baldwin: Orthopædic Department. 5 P.M., Special Lecture:—Dr. S. Taylor: Some Points in Connexion with the Circulatory System (open to all medical practitioners).

FRIDAY.—[illegible] A.M., Dr. G. Stewart: Neurological Demonstration. 12 noon, Dr. McDougal: Electrical Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 5 P.M., Lecture I.:—Mr. Baldwin: Appendicitis.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Dr. Owen: Medical Out-patients.

DAILY:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Jan. 13th.—4 P.M., Lecture:—Mr. T. Higgins: The [illegible] of Lump.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, Jan. 13th.—5 P.M., Chesterfield Lecture:—Dr. J. L. Bunch: Drug Eruptions.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

Christmas Lectures on the Haunts of Life, by Prof. J. A. Thomson—

TUESDAY, Jan. 11th.—3 P.M., Lecture VI.—The Mastery of the Air.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Jan. 11th.—4.30 P.M., Lecture:—Sir William Thorburn: Surgical Treatment of Neuralgia.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

THURSDAY, Jan. 13th.—4.30 P.M., Mr. Diggle: Diagnosis and Treatment of Carcinoma of the Larynx. (At Ancoats Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER. POST-GRADUATE LECTURE, at Whitworth-street West Branch.

FRIDAY, Jan. 14th.—4.30 P.M., Dr. Donald: Bladder Symptoms in Gynæcological Practice.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

EVANS, G. I., M.B., Ch.B. Oxon., has been appointed Resident Medical Officer to the King Edward VII. Hospital for Officers, Grosvenor-crescent.

GARSTANG, W., M.B., Ch.B. Vict., Certifying Surgeon under the Factory and Workshop Acts for Hucknall.

GODDARD, C. E., M.B., B.S. Lond., Medical Officer of Health for Harrow, in addition to Wembley.

LITTLE, P. M., M.B., Ch.B. Edin., M.C., House Surgeon to the Royal Devon and Exeter Hospital.

M'GIBBON, J., M.B., F.R.C.P.E., Professor of Midwifery in the University of Johannesburg, South Africa.

MOORE, C. A., M.S. Lond., Ch.M., F.R.C.S., Surgeon to the Bristol General Hospital.

MURRAY, J., M.B., B.Ch. R.U.I., Medical Officer of Health to the Leadgate U.D. Council.

ROGERS, Sir LEONARD, Stuart Mill Lecturer in Tropical Medicine at the London (R.F.H.) School of Medicine for Women.

STIDSTON, C. A., M.D., B.S. Lond., Honorary Surgeon to the Wolverhampton and Staffordshire General Hospital.

THWAITE, B., M.B., B.S. Lond., Physician to Out-patients to the Birmingham and Midland Free Hospital for Sick Children.

Vacancies.

For further information refer to the advertisement columns.

Altrincham General Hospital, Cheshire.—H.S. £175.

Bath, Royal United Hospital.—H.S. and H.P. £150 each.

Birkenhead Education Committee.—Asst. Sch. M.O. £450.

Bradford Royal Infirmary.—Res. Surg. O. £250. H.S. £200.

Cardiff, King Edward VII. Hospital.—H.S. £200.

Cardiff, King Edward VII. Welsh National Memorial Association.—Med. Supt. at North Wales Sanatorium, near Denbigh. £500. Tuberc. P.'s. £500. Also Asst. Tuberc. P.'s. £300.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—Res. M.O. £250.

Colonial Service.—M.O.'s for West African Medical Staff, Government Service in Malaya, East African Protectorates, West Indies (including British Guiana), Fiji, and the Western Pacific, &c.

Derby, Derbyshire Royal Infirmary.—Ven. Dis. O. £750.

Doncaster Royal Infirmary and Dispensary.—Sen. and Jun. Res. M.O.'s. £250 and £225.

Down District Asylum, Downpatrick.—Sen. and Jun. Asst. M.O.'s. £350 and £300.

Durban, Government Hospital.—Asst. M.O. £484.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. M.O. £200.

Evelina Hospital for Children, Southwark, S.E.—Hon. P. to Out-patients.

Glamorgan County Council.—M.O. £700.

Hackney Metropolitan Borough.—M.O. 10s. per hour.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. Res. M.O. £150. Also H.P.'s.

Hospital for Women, Soho-square, W.—Hon. Radiologist.

Hull Royal Infirmary.—Asst. H.S. £150.

Ilford Urban District Council.—Female Asst. M.O.H. £400.

India, Countess of Dufferin Fund.—Three Med. Women. Rs. 350 per mensem.

Kirkburton, Storthes Hall Asylum, near Huddersfield.—Asst. M.O. £400.

Lincoln County Hospital.—Jun. H.S.—£150.

Liverpool Hospital for Children, Moreton, Birkenhead.—Jun. M.O. £250.

London County Mental Hospital Service.—Sixth Asst. M.O. £300. Also Clin. Assts. £200.

Macclesfield, Cheshire County Asylum, Parkside.—Asst. M.O. £350.

Manchester, Ancoats Hospital.—H.S. £150.

Manchester, Barnes Convalescent Hospital, Cheadle.—Res. M.O. £300.

Manchester Royal Infirmary.—Accident Room H.S. £200. Also Radiological Tutor in X ray Department. £50.

Metropolitan Hospital, Kingsland-road, E.—Cas. O. and Res. Anæsth. £120.

Middlesex County Council.—Asst. M.O. £500.

Newark Hospital and Dispensary.—Res. H.S. £200.

Newport, Mon., Royal Gwent Hospital.—Jun. Res. M.O. £180.

Nottingham General Hospital.—H.S. £200.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. S.

Queen Mary's Hospital for the East End, E.—Hon. Dental S.

Royal Free Hospital, Gray's Inn-road, W.C.—H.P. £50.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. £150. Also Res. H.P. £125.
South Eastern Hospital for Children, Sydenham, S.E.—Res. M.O. £150.
Southend-on-Sea County Borough.—Asst. M.O. £500.
Sheffield Royal Hospital.—Asst. Cas. O. £150.
Stoke-on-Trent, North Staffordshire Infirmary.—H.S. £200.
Taunton and Somerset Hospital.—Res. Asst. H.S.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.P. and H.S. £100.
Warrington Infirmary and Dispensary.—Jun. H.S. £200.
Wells Asylum, Somerset.—Asst. M.O. £300.
Western General Dispensary, Marylebone-road, N.W.—Res. H.S. £250.
West London Hospital, Hammersmith-road, W.—P. Also Hon. Obstetric Registrar.
Westminster Hospital (opposite Westminster Abbey).—H.P.
Wigan Education Committee.—Asst. Sch. M.O. £500.
Willesden Hospital.—Additions to Hon. Med. Staff.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Dalmellington and at Fishguard.

Births, Marriages, and Deaths.

DEATHS.

CASTOR.—On Dec. 30th, 1920, at his residence, Lodge-road, Croydon, from pneumonia, Lieutenant-Colonel Richard Henderson Castor, I.M.S., K.I.H., aged 59 years.

CRONIN.—On Dec. 30th, 1920, at his residence, Old Manor House, Clapham, S.W., Eugene Francis Cronin, M.D., M.R.C.S.

EVANS.—On Dec. 30th, 1920, at the Mental Hospital, Brentwood, George Evans, M.B., Medical Superintendent.

FRANKS.—On Dec. 31st, 1920, at Craiglands, Rowlands Gill, Emilie, beloved wife of Dr. Charles Franks.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

SOME PROBLEMS IN MARINE HYGIENE.[1]

WITH SPECIAL REFERENCE TO MERCHANT SHIPS.

BY SURGEON VICE-ADMIRAL SIR ROBERT HILL, K.C.M.G., C.B., C.V.O.,

MEDICAL DIRECTOR-GENERAL OF THE ROYAL NAVY.

II. WATER-SUPPLY OF SHIPS AND DISEASES OF SHIP LIFE.

The Water-supply of Ships.

THE important problem of water-supply is easily solved. Many diseases, ranging from simple outbreaks of diarrhœa to cholera, the typhoid group and the dysenteries, are classed as water-borne. Metallic poisoning and many parasitic intestinal worms are sometimes water-borne. It is essential to safeguard the drinking water-supply in a ship, where the main difficulty is that of storage. In old days rain-water was collected and stored in casks; in 1772 distillation was first used in the Royal Navy, and later iron tanks were employed for storage. In all ships the water-supply should be most liberal, as in the Royal Navy.

Regulations for supply.—The rules laid down in the Merchant Shipping Act and by the Board of Trade leave a wide margin of danger. Section 206 of the former merely states that "if the inspecting officer finds that the water has not been inspected, or to be deficient in quality, the ship shall be detained until the defects are remedied to his satisfaction." The regulations for supply of drinking-water in H.M. ships are much more stringent, and I cannot do better than give a brief description of them. The lowest limit of amount provided should be 10 gallons per head per day for all purposes, increased to 12 gallons in the tropics. The storage tanks are of iron, coated with a preparation known as rosbonite, and roughly of a capacity of 30,000 gallons for 1000 men. They should be so arranged, by means of a pipe connexion for attachment to the water-boat's hose, that water can be passed from these boats to the tanks without opening the manholes, and the manholes should not be situated in a sleeping or messing compartment. These manholes should be raised into a coaming to prevent soakage of wash-deck dirt into the storage tank.

Cleansing of tanks.—Tanks should be cleaned out every six months—in merchant ships at the end of each voyage—or when known pollution has occurred. This should be done by men specially inspected for disease by a medical officer; they should wear clean overalls and sterilised rubber boots, and the cleansing should be under the supervision of a medical officer or competent executive officer. From the storage tanks the water is pumped up to gravity tanks on the superstructure of the ship; these gravity tanks are made of galvanised steel plates, and it is recommended that they be fitted with raised hinged manholes for inspection purposes. Gravity tanks seldom require cleansing; from them the water is passed through galvanised pipes to the drinking or issuing tanks in various parts of the ships convenient for the men to draw the water off. They are covered-in tanks of a capacity of from 25 to 200 gallons. In the lids of these issuing tanks is an opening for filling, protected by a perforated metal disc and funnel-shaped guard. The branch pipe from the main should end a short distance from the funnel; the latter should be fitted with a metal cover. When the drinking supply in a ship is by distillation there is little danger, but it must be remembered that leakage of salt water through cracked condenser tubes is a grave source of pollution, especially if the water is from a harbour source. Distilled water is tested for the excessive presence of common salt by the engineers during the process of distillation. Only the purest sea-water should be used for distillation; polluted harbours and rivers should not be employed.

Dangers of shore supply.—When water is brought from the shore to a ship the strictest precautions must be taken against dangers arising, firstly, at its source on shore, and secondly, in the method of transport. Strict inquiries and inspection should be made, and if the source is in any way doubtful reports of analysis should be obtained. However pure the water may be at its source grave danger may occur in transport, which is usually carried out by water-boats. It should be required by all shipping companies that these boats be modern in type, consisting of vessels containing steel tanks free of the vessel's side, with a space between to allow of inspection, and situated amidships well away from such sources of heat as the engine room aft and the pump room forward. They should have raised manholes on the top, with a coaming of at least 4½in., and with hinged water-tight cover. Canvas hoses for supply to ships are perhaps the best. No boat for the supply of drinking-water should carry water for boiler purposes as well. There should be general adoption of the special rules laid down by the Admiralty as regards the care of these boats and the cleanliness of their crews. As an example of danger arising even when the shore supply is above suspicion, this instance may be quoted. One of H.M. ships visited a certain island in the southern Indian Ocean where the shore water was very pure, but when the medical officer inspected the water-boat it was found to be of old rotten wood with unlined wooden tanks, into which sea-water leaked. When not in use the water-boat was moored in the harbour just where the town sewage was discharged.

---

[1] Being portions of a Chadwick Trust lecture delivered at Newcastle-upon-Tyne, Dec. 3rd, 1920.

Chlorination.—When all precautions are taken to ensure safety there is still an element of doubt in shore water; therefore chlorination is carried out in H.M. ships by regulation. This process is easily within the powers of any merchant ship, large or small, and should be adopted as a part of the Merchant Shipping Act. Chlorination is done simply by adding 30 gr. of chloride of lime to every hundred gallons of water when the tanks are being filled. This is best done by first making the requisite *solution of chloride* of lime and adding it to the water. The lime should be fresh and kept in amber-coloured air-tight bottles, in which manner it is supplied to H.M. ships; it rapidly loses its sterilising effect if exposed. For this reason chlorination is more efficient when use is made of liquid chlorine gas stored in cylinders; but this method has so far only been applied to the chlorination of town water-supplies. Filters should be regarded as a potential source of danger on board ship; they are frequently neglected, and have then been a means of pollution, for which reason they have been abandoned in H.M. ships.

Diseases Incidental to Ship Life.

Certain diseases appear more persistently on board ship than ashore owing to the environment of the seaman, to diet, and to climatic exposure.

Most of the common diseases from which seamen suffer are diseases of the respiratory system, including tuberculosis and influenza; overcrowding and inefficient ventilation are the causes and the means of spreading infection. Diseases directly due to faulty diet are scurvy and ship beri-beri. Diseases due to climate are numerous; malaria is pre-eminent, sunstroke or heat-stroke being a near second. Infectious and contagious diseases are very liable to spread and more difficult to control owing to the close proximity of individuals and the extreme difficulty of segregation on board ship. I propose only to deal with those diseases which will be materially affected by improvements in the construction of ships, pointing out some indications for preventive measures.

Tuberculosis.—In spite of all our modern improvements in ventilation and accommodation, this disease remains one of the chief causes of invaliding in the Royal Navy. It is unfortunate for comparison's sake that the only records available in the Merchant Service are death returns. The recent war has rendered both the Royal Navy and the mercantile records incomplete since the year 1914; it is hoped that both these will be available shortly, but they will contain abnormal returns owing to the war, and comparison will therefore be unfair. In the year 1914 the mercantile death returns under tuberculosis and phthisis amounted to 87 out of a total of 245,619 men serving, excluding fishermen. This does not sound a large number, but there must have been a large percentage of cases occurring besides those which terminated fatally. In the Royal Navy for 1914, with a total force of 158,300, there were 336 cases, with 269 invalidings and 42 deaths, the case invaliding and death ratios being 2·12, 1·69, and 0·26 per 1000 respectively, as compared with 2·35, 1·82, and 0·24, the ratios for the previous five years. These figures, if they do nothing else, show that much has yet to be done in construction to lessen the incidence. The environment of the seaman in the Mercantile Marine and in the Royal Navy must be improved. In the future ships must be constructed so that the men are given better accommodation, more natural light, and more natural ventilation, for however good artificial (or pumped) ventilation may be, it is never the same as pure fresh air.

Medical examinations.—Early recognition of the disease and prompt removal of cases from the ship will do much to diminish the incidence. Very careful recruiting is done for the Navy, quarterly examinations of men are carried out, at which weights are taken, and anything holding a suspicion of the disease is noted and the individual kept under observation and, if necessary, sent to hospital. Such measures are more difficult to undertake in the Mercantile Marine, but more could be done if shipping companies increased their medical staff ashore, and instigated a more rigorous examination of men signing on for voyages. Mercantile seamen dislike a too frequent medical examination, but this is a matter of that discipline and routine to which war service will have helped to accustom them.

Tropical diseases.—The best means of prevention of malaria on board is to construct mosquito-proofed ships for trading in malarious areas. This method is now adopted in all ships of the Royal Navy going to West Africa and Persian Gulf and other bad malarious areas; all ports and doorways are fitted with fine wire gauze, and it is recommended that shipping companies should supply similar fittings. Sunstroke and heat-stroke may be lessened by good awning provision, and the supply of some ice-making machine in ships going to tropical countries. Increased ventilation by wind-sails, wind-scoops, &c., will, of course, be essential.

Against infectious and contagious diseases in general, improved ventilation, better accommodation, and provision of adequate working facilities and latrine systems are the main preventive measures; but it is absolutely necessary that in all merchant ships some isolation space be provided where adequate temporary treatment can be given for such diseases until the case can be moved ashore; some means of steam disinfection should also be provided, as such means is now our main preventive in typhus fever. It is hoped that a simple means of steam disinfection applicable to any size of steamship will shortly be on the market, the inventor being an army medical officer. I am not at present free to describe this apparatus, as it is under trial.

Typhoid.—In addition to the precautions already named, I must mention the proved value of preventive inoculation against typhoid. Seafaring men proceeding to countries where this disease is common, such as the Eastern Mediterranean, India, and China, should be given facilities for inoculation, and its advantages should be urged upon them.

Small-pox.—Seamen are particularly exposed to small-pox in their service abroad; efficient vaccination should be one of the articles insisted upon when men are signing on for voyages abroad.

Venereal diseases.—These diseases may not be more rife amongst seafaring men than among the shore population, but in ships the treatment necessary for prevention and cure is almost nil, except, perhaps, in the largest ships. We in the Royal Navy have proved in the past that as good treatment can be given on board ship as on shore; and at present the most recent preventive and curative measures are being organised on board our ships. I would urge on the Shipping Federation and shipbuilding companies to see to it at once that such measures are installed in all merchant ships, or at any rate in those carrying a doctor. Every such ship should have an ablution cabinet or treatment centre. I can assure them that all possible help will be forthcoming from the Royal Navy. Lectures should be given by medical men to the officers and men of the Mercantile Service on this subject; and medical officers engaged by shipping companies should produce evidence of some special knowledge of these diseases and their treatment. The subject is too long for deep discussion here, but the responsibility of shipping companies extends to the provision of adequate treatment for their men when they go on shore at home and abroad. There must be no penalising, and free treatment, including drugs, should be supplied. Since it resumed its work at the termination of the war the Office Internationale d'Hygiène Publique has had under consideration the importance of the establishment and maintenance of venereal treatment centres, open to merchant sailors and watermen of all nationalities, in all the chief sea and river ports. Medical—and, if necessary, hospital—treatment and medical necessaries are all to be supplied gratuitously. The propaganda work now being carried on by the National Council for Combating Venereal Disease is ably furthering the useful preventive measures which the above office has been advocating for so many years. The Marine Department of the Board of Trade, the Ministry of Health, the Shipping Federation, and various shipping companies are now fully alive to the importance of this matter.

COLONIAL HEALTH REPORTS.

Cyprus.

IN the Government report for 1919-20 an improvement in the public health is recorded. The prevalent diseases were those of the digestive and respiratory systems, influenza, malaria, skin diseases, rheumatism, and enteric fever. An epidemic of small-pox, almost entirely confined to the Limassol district, occurred in August, 1919. There has been a steady and well-maintained decrease in the number of cases of malaria treated in Cyprus since anti-malarial measures were instituted in 1913 by Sir Ronald Ross, K.C.B., the yearly total of cases having fallen from 10,000 in 1912 to less than 2000 in 1919, whilst the "spleen rate," perhaps the best index of the incidence of malaria, has shown a proportionate decline from 17·2 in 1913 to 5·2 in 1919. A slow but steady annual reduction is observed in the number of patients admitted to the leper asylum at Nicosia. During 1919 Cyprus enjoyed complete immunity from plague, cholera, and typhus, although these diseases prevailed in neighbouring countries. The estimated population at the end of 1919 was 311,108, an increase of 4111 over that of 1918. The birth-rate for the year was 29·8 per 1000 of the population (as against 31·3 in 1918), and the death-rate was 18·5 per 1000 (as compared with 26·1 in 1918).

Bermuda.

The population at the end of 1919 was estimated at 21,869, exclusive of the naval and military establishments. The proportion of coloured persons to white is about 2 to 1. In 1911 the population was 18,994, and has been gradually increasing since. The increase for 1919 was, however, the lowest on record, being only 29. This was partly due to the cessation of immigration from the West Indies owing to additional restrictions placed on immigrants and the insistence upon a money deposit on entry. The number of persons leaving the colony, especially among the labouring and domestic servant classes, is causing some anxiety. There has always been a comparatively regular and considerable immigration to the United States and elsewhere, but hitherto it has been counterbalanced by the entry of immigrants from the West Indies. The high wages prevailing in the United States of America are the principal attraction, and the bulk of those who leave the colony do not return. The population is large for the area, and the figures given take no account of the large number of tourists visiting the place, amounting in some years to more than the resident population. The birth-rate in 1919 was 24·87 per 1000 and the death-rate 17·28, both rates being considerably higher among the coloured population than among the whites. The infantile death-rate was 16·6 per 100 living births—6·1 among whites and 20·5 among coloured children. In 1919 rain fell on 183 days, the total fall for the year being 48·84 inches. The highest temperature was 90·2° F. on August 20th, and the lowest 46·8° on Feb. 12th. The colony offers unusually favourable health conditions. There are no extremes of temperature, and it is beyond the range of the usual tropical diseases. Malaria is unknown, but there are occasional outbreaks of a mild type of dengue fever. Mosquitoes are prevalent in summer, but as they are regarded more as a nuisance than as a menace to health it is difficult to arouse interest in measures for their eradication. It would, however, add greatly to the attractions of the islands and to the amenities of life if these pests could be eliminated or substantially reduced, and measures to that end are now under consideration. The reduction of the common house-fly, which is very numerous in summer, is an equally important object of the proposed measures.

Fiji.

In his report on the Blue-book for 1919 Mr. T. E. Fell, Colonial Secretary, states that the estimated population at the end of the year was 163,847 (as against 139,541 at the Census of 1911), comprising 4584 Europeans, 2824 half-castes, 62,640 Indians, 2664 Polynesians, 87,493 Fijians, 2157 Rotumans, 892 Chinese, and 613 others. The early months of the year were marked by the epidemic of influenza, which continued its ravages until March, when it gradually subsided. Medical relief parties from New Zealand and Australia, under Colonel Jennings and Major Alexander respectively, continued their good work until the end. Medical officers generally worked at exceedingly high pressure, and in many districts under stupendous difficulties, arising from the lack of means of conveyance. Their efforts, together with those of voluntary workers organised by European committees for service throughout the group amongst natives and Indians, were the means of saving many lives. The estimated number of deaths from the disease was 8145, the European victims being 1·41 per cent. of population; half-castes, 2·75; Fijians, 5·66; Indians, 4·17; and others, 6·93.

In the Colonial Hospital in 1919 1965 patients were treated, of whom 180 were Europeans. At the branch hospital at Levuka the admissions during the year were 496. Native Fijians generally derive medical treatment at the 11 provincial hospitals controlled and supervised by district medical officers. Some of the latter were still absent on war service, and in those areas the hospitals were left in charge of native medical practitioners. The number of admissions to provincial hospitals was 2816. The lunatic asylum at Suva, under the management of the resident medical officer of the Colonial Hospital, who acts as superintendent, and a board of visitors, receives patients of both sexes of all nationalities. There is separate accommodation for Europeans. The inmates numbered 70 at the close of the year. The leper asylum on the island of Makogai contained at the end of the year 352 inmates under the management of the superintendent, Dr. F. Hall, and six European nursing sisters supplied by the Catholic Mission, and five Fijian nursing sisters, all greatly devoted to their good work. The high degree of efficiency which has marked the institution since its inception has been maintained. During the year 11 lepers were conditionally discharged from the asylum.

The total rainfall recorded at Suva in 1919 was 138·18 in., as against 103·84 in. in 1918 and 162·05 in. in 1917. This rainfall is 25 in. above the average for 25 years and fell on 248 days. The average temperature for the year at Suva was 76·3° F., the mean shade temperatures being 71·3° minimum and 81·3° maximum.

Basutoland.

In his report for 1919-20 Mr. J. P. Murray, Government Secretary, writes: The anticipated recrudescence of typhus fever occurred early in January, 1919, in the same neighbourhood that the disease first appeared in 1918—viz., the Quthing district along the Orange River. There were no cases in the Qacha's Nek district. The epidemic was of a much milder type. There were 243 cases with only 50 deaths, compared with 241 cases and 111 deaths in 1918. The mildness of the epidemic renders it more difficult to deal with, as it is often weeks before outbreaks are reported, generally in some remote mountain village. In spite of vigorous efforts made to stamp out the disease it is feared that it will be found endemic in the Quthing district as it has become in some of the native territories of the Union. It is still the Tembu who are the chief sufferers, due to the dirty habits and surroundings of this clan, as opposed to the Basuto, who are naturally a clean race. Tuberculosis is neither increasing nor decreasing, the number of cases being about the same from year to year. Syphilis is becoming an increasingly serious problem and danger to the nation. 4216 cases were treated, but these must form a small percentage of the total number of cases in the territory. The type of disease is altering slightly. Formerly primary sores were seldom observed; now they are common and present the usual classical symptoms. There was no recrudescence of the severe type of influenza which devastated the country in 1918, but a fair number of cases of the usual mild form of the disease were observed; this type may be regarded as endemic. There were only 87 cases of enteric fever recorded. A dry summer and autumn is always followed by a low incidence of enteric. Where it had been possible to provide preventive inoculation, as on the Government reserve, cases were practically unknown. Dysentery was unusually prevalent, mostly of the bacillary type. There were no cases of small-pox, but chicken-pox was prevalent in some areas. During the 12 months ended March 31st, 1920, there were 62 new cases admitted to the leper settlement, and the total of inmates on April 1st was 349 (168 males and 181 females). There are still a good number of lepers at large.

HOME SERVICE AMBULANCES.

ON the release from war work of the ambulances of the Joint Committee of the British Red Cross Society and the Order of St. John the Home Ambulance Service was established to alleviate suffering by provision of transport for the sick and injured throughout the country. Its aim is a distribution of ambulances on such a scale that wherever illness or accident may occur there shall be a motor ambulance within a convenient distance to convey the patient with a minimum of pain to the point where medical and surgical skill can be most efficiently applied. The Hon. Sir Arthur Stanley is chairman of the Home Service Ambulance Committee, Sir Dawson Williams is the medical member, and Mr. F. C. Davies secretary. A list is now issued, arranged on a county basis, showing where the ambulances are stationed, and to whom application should be made for them. Applications from the London Area should be made to the Secretary of the Home Service Ambulance Committee at 19, Berkeley-street, London, W. 1. (Telegrams: Assistance, Piccy, London. Telephone: Mayfair 345.) The following example will show how the county list is set out:—

BEDFORDSHIRE.

Co. Director: Lt.-Col. F. A. Stevens, C.B.E.
Address: The Shire Hall, Bedford.
Telegrams: The Shire Hall, Bedford.
Telephone: Bedford 143.

District.	*Stationed at—*	*Officer in Charge.*
Luton.	Police Station Garage. Tel. No.: 39.	Chief Constable, Luton.
Morbanger.	Moggerhanger Park, Nr. Sandy. Tel. No.: Sandy, 25.	Dr. Welch, M.O.H. Tel. No.: Bed. 341.
Dunstable.	The Hospital, Dunstable. Tel. No.: 72.	The Matron (same address).
Leighton Buzzard.	Messrs. Parrot and Janes, North-street. Tel. No.: 122.	Chairman of the U.D.C., Council Offices, Leighton Buzzard.
Biggleswade.	Isolation Hospital, Potton-road. Tel. No.: 25.	Henry Chaundler, Esq., Biggleswade Joint Hospital Board, Biggleswade. Tel. No.: 6.

DIET KITCHENS FOR FRENCH HOSPITALS.

THE close association of the British and French Red Cross volunteers during the war has had many happy results for both countries. Amongst these must be counted the introduction of the diet kitchen into French hospitals. This essential institution was added to the equipment of French military hospitals during the war through the initiative of Miss Madge Oliver. Dr. Marcel l'Abbé, writing in *La Presse Médicale* for Dec. 22nd, 1920, describes how he was impressed with their value during the war to such an extent that he has now succeeded in arranging the transfer of their organisation to the Hôpital de la Charité at Paris. A series of diets are tabulated, so that the prescribing physician has merely to indicate a number on the diet sheet, as has long been done in many English hospitals.

GERMAN MEDICAL TERMINOLOGY.

STUDENTS of contemporary medical literature, who are otherwise fairly well versed in modern languages, are apt to find names or phrases or turns of expression in foreign journals for which the ordinary dictionary affords them no help. In French the noble series of reference books issued by the Librairie Larousse is the standby in such emergencies. In German medicine and the allied sciences nothing can take the place of Dr. Walter Guttmann's "Medizinische Terminologie," a new edition of which has just appeared (Urban and Schwarzenberg. 1920. Pp. 1311. M.90). The book appeared first in 1902, the author setting himself the task of providing short but clear definitions, and avoiding "every unnecessary ballast," but at the same time inserting any doubtful or interesting etymology, and the names of laws, symptoms, or phenomena associated with their discoverers. In later editions short biographical notices were added and the range of subject was increased, pharmacology, neurology, and medical zoology receiving special attention. Some 450 small illustrations of a rather trivial nature serve to break up the text; it is curious how the encyclopædic dictionary with really well-chosen pictures is still to be sought in any language. Although neither paper nor binding of the present edition of Guttmann is of good quality, all the essentials of convenient arrangement and easy reference are present.

SWISS SPAS.

WE have received an elaborate brochure from the pens of 12 Swiss M.D.'s and one Ph.D. describing the attractions offered by Switzerland in the way of natural medicinal waters. The following nine stations are included: (1) Eaux thermales de Baden; (2) Bex-les-Bains; (3) Bains du Gurnigel; (4) Bains de Passugg; (5) Eaux thermales de Ragaz-Pfæfers; (6) Bains salins de Rheinfelden; (7) St-Moritz-les-Bains; (8) Tarasp-Schuls-Vulpera-les-Bains; (9) Bains de Val Sinestra. Some of these are of very ancient reputation. Tacitus mentions the waters of Baden, and the bath at Pfæfers was founded in 1038. Dr. H. Keller contributes a careful analysis of the saline and other constituents of the waters with admirably clear percentage charts, from which emerges the following working classification:—

1. Eaux thermales simples: *Ragaz-Pfæfers.*

2. Eaux alcalines: (a) Alcalines terreuses: *Passugg:* source Hélène. (b) Alcalines chlorurées sodiques: *Passugg:* sources Ulricus et Fortunatus. (c) Alcalines-chlorurées sulfatées sodiques: *Tarasp-Schuls-Vulpera:* sources Lucius, Ursus, Emerita et "Neue Bulquelle."

3. Eaux sulfureuses: (a) Eaux sulfureuses thermales: *Baden.* (b) Eaux sulfureuses froides: *Gurnigel.*

4. Eaux chlorurées sodiques ou salées: *Rheinfelden, Bex.*

5. Eaux ferrugineuses: *Saint-Moritz:* sources Surpunt, Mauritius et Paracelsus. *Tarasp-Schuls-Vulpera:* sources Boniface, Carola, Val Fuschna, Sotsass, Val Plavna, Val Pizza et Wy. *Passugg:* source Belvedra.

6. Eaux iodurées: *Passugg:* source Fortunatus. *Tarasp-Schuls-Vulpera:* source Lucius.

7. Eaux lithinées: *Tarasp-Schuls-Vulpera:* source Lucius. *Passugg:* source Fortunatus.

8. Eaux arsenicales et ferrugineuses: *Val Sinestra:* sources Ulrich, Jean, Conradin et Thomas.

There follows a very practical list of the foreign (i.e., non-Swiss) spas which the Swiss resorts may adequately replace.

1. *Ragaz-Pfæfers* may replace Badenweiler, Schlangenbad, Warmbad près Wolkenstein, Warmbrunn, Wildbad (Germany); Gastein (Austria); Luxeuil, Plombières (France); Cormano (Italy); Buxton (England).

2. *Passugg: source Hélène:* Apollinarisbrunnen, Gerolstein, Neuenahr, Salzmatt, Obersalzbrunn (Germany); Bilin, Giesshübel (Austria), Vals and Vichy (France). *Sources Ulricus et Fortunatus:* Wildungen, source Hélène, Fachingen, Ems, Roisdorf, Nieder-Selters (Germany); Gleichenberg (Austria); Royat and Vichy (France).

3. *Tarasp-Schuls-Vulpera: sources Lucius, Ursus, Emerita et Neue Bulquelle:* Bertrich, Elster, Kissingen and Grenzach (Germany); Franzensbad, Marienbad, and Karlsbad (Czecko-Slovakia); Brides-les-Bains (France); Cheltenham and Leamington (England).

4. *Baden:* Aix-la-Chapelle (Germany); Herkulesbad, Budapest-[illegible], Pistyan (Hungary); Aix-les-Bains, Amélie-les-Bains, Bagnères-de-Luchon, Bagnols-Lozère, Eaux-Bonnes, Saint-Gervais (France); Acqui, Vinadio, Viterbo (Italy); Panticosa (Spain); Hélouan (Egypt); Brousse (Asia Minor).

5. *Gurnigel:* Nenndorf (Germany); Allevard, Enghien, Pierrefonds (France); Harrogate (England); Tabiano (Italy); Santa Agueda (Spain).

6. *Rheinfelden et Bex:* Dürrheim, Kreuznach, Nauheim, Reichenhall, Kösen (Germany); Ischl (Austria); Biarritz and Salies-de-Béarn (France); Salsomaggiore and Monte-Catini (Italy); Droitwich, Nantwich, Woodhall Spa (England).

7. *St. Moritz-les-Bains:* Antogast, Petersthal, Rippoldsau, Pyrmont, Schwalbach, Steben (Germany); Franzensbad and Marienbad (Czecko-Slovakia); Forges and Lamalou (France); Recoaro (Italy); Tunbridge Wells (England); Spa (Belgium).

8. *Val Sinestra:* Cudowa, source Guber (Silesia), Levico Roncegno and Recoara (Italy); Vichy, La Bourboule, Mont Dore, Royat and Vic-sur-Cère (France).

Of course, the indications are reversible, and we may suggest on our part that *Buxton may replace Ragaz* and so on. We cannot, however, with justice make quite the same claim as Switzerland does to the position of international health resort, for Dr. Zollinger writes:—

> Pendant toutes les tempêtes politiques qui ont secoué le monde, la Suisse a donné la preuve que des peuples de langues et de caractères différents peuvent travailler en harmonie à la formation d'un état; elle a prouvé victorieusement qu'elle peut devenir un digne membre de la grande communauté des peuples et qu'elle peut être un élément de forces constructives dans l'élaboration du statut de l'humanité de demain.

Nor can we provide to the same extent certain other curative factors set out as: Le soleil et la lumière, l'air pur des montagnes, la chaleur et le froid, facteurs qui constituent la climatothérapie et l'héliothérapie.

A Radiant Heat Conserver.—Mr. C. Wray's device, described in our last issue, may be obtained through the Canadian United Manufacturers Agency, Ltd., of 12, Charterhouse Buildings, Goswell-road, London, E.C. 1.

S.M.O.—The principal part of the Porteus outfit for mental deficiency is the so-called maze test. Apparently this can only be obtained from the Vineland Training School, New Jersey, U.S.A.

Corrigendum.—In Major H. C. Brown's paper on "The Use of Citrated Media," published in our last issue, "lead acetate" in the eleventh line from the bottom, column 1, p. 23, should read "lead *citrate.*"

ARMY MEDICAL COLLEGE LIBRARY

A Statistical Investigation

OF

RECORDS OF TREATMENT AND BLOOD EXAMINATION IN 18,731 CASES OF MALARIA.

BY J. PRATT JOHNSON, *M.C.*, M.B., B.S. LOND., D.P.H. OXF.,
D.A.D.M.S. (PATHOLOGY), MAJOR, S.A.M.C.;
AND
KENNETH GILCHRIST, *M.C.*, M.B., CH.B. EDIN.,
MAJOR, S.A.M.C.

THESE investigations were carried out during the war on cases of malaria returned from the German East African campaign and admitted for treatment into military hospitals in South Africa. A routine system of blood examination was instituted, each man's blood being examined by the thick-film method on admission and subsequently at weekly intervals. Special malaria cards on which laboratory reports and records of treatment were kept were taken out for each man, and provided ample material for statistical research. These cards on sorting gave the following groups:—

Classification of Series.

1. Total cards analysed	18,731
2. Total cards clinically diagnosed malaria with negative smears ("negative cards")	9,943
3. Total cards diagnosed malaria with positive smears ("positive cards")	8,788
4. *Total smears carried out in series*	74,022
5. Positive cards—	
(*a*) Benign tertian	5,393, or 61%
(*b*) Malignant subtertian	1,977, or 23%
(*c*) *Mixed infections* (B.T. and M.T.)	1,418, *or* 16%

The large number of *mixed infections indicates that infection with one type of malaria in no way protects against invasion with another.* The converse is more likely to be true; the debility produced by malarial infection naturally reduces the effectiveness of the protective mechanism.

ROUTINE TREATMENT OF MALARIA.

The earlier records of this series showed marked variation in the actual dosage of quinine employed and in the duration of quinine treatment. A dosage of quinine of 5 or 10 gr. daily was frequently recorded, and was commonly associated with repeated relapses and progressive anæmia. *Whatever may be said for the successful employment of such doses in mild cases of malaria, they were found to be totally inadequate for the severe massive and mixed infections commonly observed in troops invalided from the German East African campaign.* Apart from the necessity of controlling infection as early as possible from the point of view of the ultimate cure of the disease, the question arose of undue pressure on the hospitals owing to the increased period in hospital of each case inadequately treated.

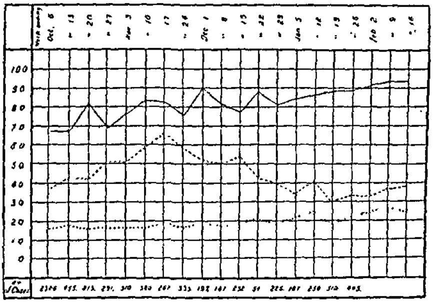
In November, *1917, definite instructions for the* routine treatment of malaria were issued. All ordinary cases, irrespective *of type, were ordered 10 gr. of* quinine in solution three times daily *for three weeks, followed* by the same dose twice daily for one month and then 10 gr. daily for two months.

The beneficial effects of the increase of quinine employed in all cases of malaria is reflected in Chart 1. It will be observed that an increase in the number of days on which quinine was administered and the average daily dose of quinine is associated with a reduction in the number of days in hospital, and that the percentage number of days in hospital on quinine in October, 1917, rises from 67 per cent. of the total stay in hospital to over 92 per cent. in March, 1918. The average amount of quinine administered in all cases of malaria similarly rises from 16 gr. per case per day in October to 23 gr. per case per day in April. The gradual rise in these factors is accompanied by a gradual fall in the average period in hospital of all cases.

Period in Hospital of Each Type of Malaria.

It should be borne in mind that the same standard of clinical fitness and two consecutive negative smears at weekly intervals was required of all cases before discharge, irrespective of the particular type of malaria recorded. Furthermore, with regard to treatment, although the average daily quinine employed shows a gradual rise the increase applies generally to all cases of malaria. Under these circumstances, for the same period the average duration of treatment of each type of malaria before discharge reflects—with a considerable degree of accuracy considering the large number of cases in each group—the relative resistance of each type of malarial infection to treatment. It should also be remembered that practically every man admitted to hospital had suffered at some time or other during the campaign from attacks of malaria. Table I. summarises the results of analysis in each type of case.

CHART 1.



Showing the beneficial *effect of increase of quinine dosage on* the length of malaria attack as evidenced by the number of days in hospital. Upper line = percentage number of days in hospital on quinine. Middle line = average number of days *in hospital per* case. Lower line = daily average grains quinine per case. The figures below the chart give the actual number of cases.

TABLE I.—*Relation between Quinine Treatment and Days in Hospital in 4905 Different Infections.*

Type of case.	No. of cases.	Average daily quinine (gr.)	Average days in hospital.
Benign tertian	1670	24·7	45·4
Malignant subtertian	473	25·2	43·6
Mixed infection (B.T. and M.T.) ...	318	24·2	63·1
Total positives...	2461	24·7	47·3
"Negative" cases	2444	22·5	32·3
All cases	4905	23·9	39·9

In reviewing the above figures *it is clear that:* (1) Mixed *infections are more resistant to treatment than either* B.T. *(benign tertian), or* M.T. *(malignant subtertian)*; (2) B.T. is as resistant or even more resistant than M.T., when the question of parasitological and clinical relapse is taken into consideration.

Benign tertian and malignant subtertian infections.—The ready response of B.T. infections (excepting chronic resistant cases) to quinine administration is reflected more in the rapid disappearance of parasites from the finger blood than in the freedom from relapses. M.T. infections, although in the first place more obstinate and difficult to eradicate from the finger-blood, once controlled, are far less prone to relapse. It should be noted that the occurrence of a parasitological relapse prevented the discharge of a patient in military hospitals until two consecutive negative blood reports had been recorded, although negative tests may have been recorded previous to the relapse. The long period of detention of benign tertian cases is largely due to the high percentage of relapses both clinical and parasitological which occurred in this infection.

Mixed infections.—The prolonged treatment required in mixed infection (M.T. and B.T.) is due partly to the resistance of these infections to the action of quinine, and partly to the frequency with which relapses of either one or the other (usually benign tertian) infection takes place. Almost without exception the occurrence of two types of malaria together in the same patient increases enormously the difficulty of control and eradication of either infection, and indicates a less favourable prognosis than in the case of pure infection with any one type.

Syphilis and malaria.—The resistance of malarial infections, even when involving one type only of malaria, in syphilitic subjects is very marked. Relapses are frequent and anæmia severe. The natural protective forces of the body are reduced in effectiveness by any debilitating influence. The chronicity of malaria in syphilitic subjects, in spite of thorough antisyphilitic and of antimalarial treatment, emphasises the importance of the natural protective mechanism of the body in combating malaria and in rendering effective the administration of quinine.

PARASITOLOGICAL RELAPSE UNDER QUININE TREATMENT.

Viewed in the somewhat indefinite light of ordinary clinical interpretation the word "relapse" would appear to imply a recurrence of acute symptoms in a resolving pathological condition which otherwise might reasonably have been expected to proceed to complete cure. The "relapse" of malaria, however, does not admit of such simple and precise interpretation, for it need not imply the presence of subacute or even chronic symptoms prior to the onset of the more acute manifestations; nor need it imply that a complete cure might reasonably have been expected. Relapses in malaria are the acute exacerbations of an otherwise continuous, and it may be entirely latent, systemic infection, where sooner or later the recurrence of acute manifestations is the invariable rule. Moreover, the term "relapse" is used not only where the latency interval is ten days to two or three weeks, but similarly to indicate an acute attack supervening after a latency interval free of all malarial symptoms extending over a period of from one or two months to one or two years.

Classification of Relapses.

(1) *Clinical or pyrogenic relapse.*—A recurrence of fever and its associated acute symptoms after a period of quiescence constitutes the true clinical relapse of malaria. Parasites are present in the peripheral blood.

(2) *Parasitological relapse.*—The reappearance of asexual parasites in the peripheral blood after one or more consecutive negative findings constitutes "parasitological relapse," which frequently occurs without clinical relapse, but will include any clinical relapse which may take place, its recorded duration being longer. For the parasitological relapse, based entirely on parasitic findings, embraces the whole period of the persistence of asexual parasites in the peripheral blood, and parasites can be demonstrated in the blood for some days before the onset and for a varying period after the subsidence of clinical symptoms. Frequent relapse is a clear indication that the host's defensive mechanism and any remedial measures adopted have failed to control the vegetative activities of the parasite. It is most prone to occur in untreated infections, in massive multiple, and particularly in mixed infections, in conditions of low vitality, and especially in the presence of a debilitating disease, such as syphilis. During the interval between attacks the parasites may either fall below the "detectable limit" or persist in numbers well above this limit.

In quiescent chronic malaria there exists a condition of armed neutrality—of temporary adaptation of host to parasite, of parasite to host. The extraordinary power of persistence exhibited by malarial infections, in spite of sustained and vigorous treatment, is a characteristic [illegible] the disease—a characteristic single, significant, [illegible]ant; a characteristic which demands cautious [illegible]ance and careful investigation of all so-called [illegible]" of malaria. It is common knowledge that all other protozoal diseases of man and the lower animals exhibit tenacious persistency and are difficult of eradication.

Variations Presented by a Subclassification of Parasitological Relapse.

(*a*) Relapses to same type—simple infection:—

1. Malignant subtertian to malignant subtertian.
2. Benign tertian to benign tertian.
3. Mixed (M.T. and B.T.) to mixed (M.T. and B.T.).

(*b*) Relapses to different type—mixed infections:—

1. Benign tertian to malignant subtertian.
2. Malignant subtertian to benign tertian.
3. Mixed to benign tertian.
4. Mixed to malignant subtertian.
5. Malignant subtertian to mixed.
6. Benign tertian to mixed.

(*c*) Relapse from negative smears:—

1. Negative to malignant subtertian.
2. Negative to benign tertian.
3. Negative to mixed.

In examining the following tables it should be remembered that (1) these final figures are obtained by reduction from numerous preliminary detailed tables (unpublished). It is not possible to employ the results in one table in association with the results in any other table; and that (2) the total number of cases investigated vary in different tables owing to the fact that the data available in some cards are not sufficiently complete for all investigations, but may provide facts which can be utilised for statistical purposes. For example, a card may show full records of the various blood examinations made, but the records of the treatment given during the whole period of stay in hospital may be incomplete. Such a card would be of service for an investigation of parasitological relapse, but would be of no value in a correlation of relapse incidence and quinine dosage.

TABLE II.—*Final Analysis of 1281 Relapses under Quinine to Same Type of Cases Positive on Admission: Analysed Totals.*

Type of relapse.	Before parasite relapse—	
	Average interval under treatment.	Average daily quinine.
M.T. to M.T. (156 relapses)	17 days.	21 gr.
B.T. to B.T. (1112 relapses)... ...	18 ,,	23 ,,
Mixed to mixed (13 relapses)	18 ,,	21 ,,
1281 relapses	18 ,,	23 gr.

TABLE III.—*Final Analysis of 399 Relapses under Quinine to Different Type of Cases Positive on Admission: Analysed Totals.*

B.T. to M.T. (116 relapses)	15 days.	20 gr.
M.T. to B.T. (144 relapses)	16 ,,	22 ,,
Mixed to B.T. (62 relapses)	21 ,,	20 ,,
Mixed to M.T. (24 relapses)	20 ,,	17 ,,
M.T. to mixed (22 relapses)	12 ,,	18 ,,
B.T. to mixed (31 relapses)	18 ,,	20 ,,
All positive cases relapsing to different type (399 relapses)...	17 ,,	21 gr.

TABLE IV.—*1276 Cases Negative on Admission Relapsing under Quinine to Different Types: Analysed Totals.*

Malignant subtertian. (232 cases)...	12 days.	20 gr.
Benign tertian. (995 cases)	14 ,,	20 ,,
Mixed infections. (B.T. plus M.T.) 49 cases ...	14 ,,	21 ,,
All cases negative on admission relapsing under treatment (1276 cases)	13 ,,	20 gr.

Frequency of Relapses Under Quinine in Each Type of Malaria.

The final results arrived at from an analysis of 2649 relapses occurring in a series of 14,802 cases of malaria under treatment in military hospitals are as follows.

Percentage Relapse Incidence.

1. All relapses in series—2649 out of 14,802 cases, or 17·9 % relapsed.
2. Of cases with initial negative smears... ... ... 14·1 % ,,
3. Of cases with positive smears ... ... 23·7 % ,,
4. In benign tertian malaria—
   881 out of 3877 cases, or 23·8 % ,,
5. In malignant subtertian malaria—
   143 out of 1565 cases, or 11·2 % ,,
6. In mixed B.T. and M.T. malaria—
   393 out of 1232 cases, or 39·4 % ,,

An examination of these figures indicates that the most intractable type of malaria from the point of view of control and prevention of relapses is a mixed infection of benign tertian and malignant subtertian. Moreover, the chances of relapse are more than twice as great in benign tertian than in malignant subtertian. The lower percentage incidence obtaining in cases with initial negative smears indicates that this group included the lighter infections, which were more easily controlled by the routine treatment employed in all military hospitals. The percentage of relapses in cases diagnosed clinically but not microscopically as malaria approximates sufficiently to the percentage relapses in malarial cases in which the diagnosis was proved microscopically to support the conclusion that the negative cases included in this series are cases of malaria. If cases wrongly diagnosed as malaria had been included the percentage relapses would be reduced to a figure markedly below that for known positives. All cases included in this series were troops returned from the German East African campaign; practically all had at some time suffered from malaria.

TABLE V.—*Relapse Analysis in Different Infections (6674 Cases) under Quinine.*

Infection.	Total cases positive on adm.	Total cases relapsing.	Av. No. relapse per case.	Cases relapsing per cent.	Av. relapse interval (days).	Av. daily quinine per case during interval.	Av. No. of days in hospital.
B. T.	3877	881	1·3	23·8	17·9	23·0 gr.	47·5
M. T.	1565	143	1·2	11·2	16·4	21·3 ,,	45·5
Mxd.	1232	393	1·1	39·4	16·7	20·6 ,,	66·3

The relapse-rate in each type per week is as follows:—Benign tertian, 3·5 per cent.; malignant subtertian, 1·7 per cent.; mixed infection (M.T. and B.T.), 4·1 per cent.

TABLE VI.—*Correlation of Quinine Treatment, Period in Hospital, and Relapses under Quinine.*

(A) *Cape Coloured Corps (All Types of Malaria).*

Period of observation.	No. of cases.	Per cent. relapses.	Average daily quinine.	Average period in hospital.
June–July, 1918	124	32·3	21·8	70
August, 1918	223	19·7	26·9	42
September–October ...	345	17·6	27·1	46
—	693	21·0	25·0 gr.	49 days.

(B) *Europeans (All Types of Malaria).*

Period of observation.	No. of cases.	Per cent. relapses.	Average daily quinine.	Average period in hospital.
January to March, 1918..	1871	18·8	23·8	38
April to June, 1918	919	11·1	23·5	31
July to September, 1918..	520	11·9	25·9	36
—	3310	15·6	24·0 gr.	36 days.

(C) *Benign Tertian Malaria: in Cape Coloured and Europeans.*

Race.	No. of cases.	Per cent. relapses.	Average daily quinine.	Average days in hospital.
Cape coloured	334	36	26 gr.	51
Europeans	1080	32	25 gr.	40

The relapse statistics in regard to the Cape Coloured Corps are of interest in view of the fact that an increase in daily quinine dosage from 21·8 gr. to 27·1 gr. is associated with a fall in the average period in hospital from 70 to 46 days and a reduction in the percentage relapses from 32·3 per cent. to 17·6 per cent. It will be observed that for the same type of malaria (benign tertian) the relapse incidence and average stay in hospital are greater for the Coloured Corps as compared with the European figures. This divergence would appear to be partly accounted for by the lessened resistance exhibited by coloured races to infectious diseases.

Relapse Interval.

It is necessary to emphasise that the relapse interval of these records refers only to parasite relapses under quinine, which may be considered to be more reliable data for study than records of clinical relapses unsupported by microscopical examination. The average number of days of the relapse interval are as follows: Benign tertian relapse: from initial negative smear, 14 days; from initial positive smear, 17·9 days. Malignant subtertian relapse: from initial negative smear, 12 days; from initial positive smear, 16·4 days. Mixed infection (M.T. and B.T.) relapse: from initial negative smear, 14 days; from initial positive smear, 17 days.

PERSISTENCE OF ASEXUAL PARASITES.

Before discussing the question of the persistence of asexual forms in the peripheral blood it is necessary to state that in all cases under examination included in this investigation the *thick film* was used throughout. The information available from weekly analyses, apart from its interest from a research point of view, supplied valuable indications as to the results obtained in each area from the treatment administered. In view of the almost universal prejudice of the soldier against quinine, and the firm belief held by some that quinine is distinctly harmful and liable to cause heart disease, it was necessary to exercise the greatest vigilance in regard to its administration. The persistence of parasites in the blood over a long period focussed attention on these cases, and resulted in either an alteration or modification of treatment, or discovery of a patient who was deliberately but covertly avoiding his doses of quinine. The fact that except in unusually chronic cases asexual parasites are not found in thick smears after a few days' administration of quinine raised the question as to what proportion of these cases in which asexual parasites persisted indefinitely in the blood were due to avoidance of quinine. Accordingly a system of recording each dose administered to each patient was instituted in one hospital, the quinine being administered in solution; each dose was actually seen to be swallowed and was then noted.

The results obtained in this hospital were in accordance with those generally obtained in the treatment of malaria in military hospitals in South Africa. Records of presence or absence of parasites in finger blood were available at about weekly intervals; cases responding to treatment were separated from resistant cases, and especial attention was thus secured for the latter group.

It should be noted that in each type of malaria the interval between blood examinations is less than the average relapse interval, so that although records of daily blood examinations were not available it is reasonable to assume the presence of parasites in the blood on the days intervening between two positive examinations, especially in view of the large proportion of heavy and resistant infections.

Final results of analyses of the records with regard to persistence of asexual parasites are set out in the following tables:—

TABLE VII.—*Persistence of Asexual Forms under Quinine.*

Type of malaria.	Total of cases.	Average interval between blood examinations.	Cases positive on re-examination.		Average persistence of asexual forms in cases positive on re-examination.
			Number.	Per cent.	
Malignant subtertian	591	8 days (21·4 gr.*)	82	14	16 days.
Benign tertian	3171	8 ,, (23·2 gr.*)	710	22	19 ,,
Mixed M.T. and B.T.	281	8 ,, (20·6 gr.*)	155	55	22 ,,
All types positive on admission...	4043	8 ,, (22·7 gr.*)	947	23	19 days.

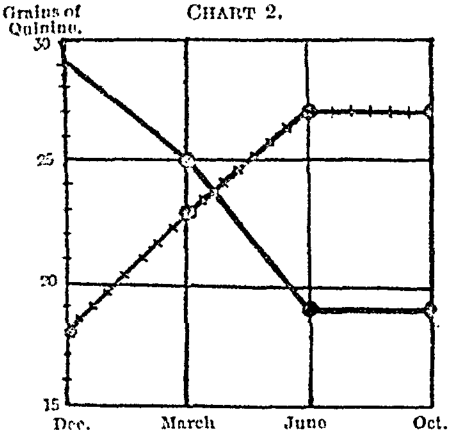
* Average daily quinine in interval.

Owing to continued pressure on the "small dosage" school the average daily quinine in all cases showed a gradual rise. This desired result was further assisted by the issue of definite instructions laying down a "standard" treatment for malaria. Table VIII. is an analysis of 4013 cases indicating that the rise in quinine was associated with a marked reduction in the number of positive cases remaining positive at the end of eight days' treatment.

TABLE VIII.—*Results in 4013 Malaria Cases Admitted to Hospital with Positive Smears on Re-examination After an Average Interval of Eight Days' Quinine Treatment.*

Three months ending—	Number of cases.	No. of cases positive on re-examination.	Per cent. positive on re-examination.	Average daily quinine.
Dec. 29th/17 ...	1031	313	29%	18 gr.
March 30th/18	1491	368	25%	23 ,,
June 29th/18 ...	900	160	19%	27 ,,
Oct. 5th/18 ...	562	106	19%	27 ,,

CHART 2.



Showing how a rise in quinine is associated with reduction in the number of positive cases remaining positive at the end of eight days' treatment. Hatched line = average daily quinine in interval between examinations. Continuous line = percentage cases positive on re-examination.

It will be observed that of 4013 cases of malaria admitted into hospital with positive parasite findings 23 per cent. show parasites persisting in the blood on the 8th day in spite of an average daily dose of quinine of 22·7 gr. The average persistence of parasites in the finger blood in these cases was 19 days. This fact indicates the severe nature of the malaria cases admitted to military hospitals, and demonstrates the ineffectiveness and slow action of quinine in destroying malaria parasites in unhealthy and debilitated individuals.

Recent publications viewed from the point of view of the specific action of quinine disclose a certain degree of shaken confidence in the parasitotropic value of this drug. Quinine is undoubtedly the most valuable single remedy at present known, but its repeated failure to eradicate malaria, even when exhibited in doses and amounts limited only by the toxicity of this drug, indicates that unless it is aided by the natural protective mechanism of the body frequent relapses and long-continued illness occur, as was clearly shown in recent campaigns in malarial countries; the exigencies of military service gave rise, especially in the tropics, to conditions in which the individual's natural resistance to disease is reduced to the minimum. In the German East African campaign, owing to the extreme exhaustion of the troops admitted to field hospitals for treatment, the action of quinine could not be described as more than palliative, most cases progressing to massive infections, frequently relapsing, which were not reduced until better health conditions—as on turn to South Africa—gradually engendered a more ctive natural resistance. It seems highly probable the latter is largely represented by "phagocytosis." is possible that the action of quinine in malaria nalogous to the action of opsonins on bacteria in infected tissues. Parasites damaged but not destroyed by quinine may then be actually ingested and destroyed by phagocytosis. There appears to be no doubt that the leucocyte is of paramount importance in the prevention and cure of malaria. Perusal of published works on malaria, particularly those of the earlier writers, leaves the impression that parasites disappear from the finger blood soon after the administration of quinine. The above figures show that on an average in 4043 cases parasites could still be demonstrated in 23 per cent. of cases when examined after an average interval of eight days, and that the parasites in these resistant cases persisted for an average period of 19 days, treatment being 22·7 gr. of quinine per day. In considering this apparent anomaly it is necessary to bear in mind the following points: (1) In this series the thick-film method is used for diagnosis which increases the chance of a positive result by about 30 times, and in the publications referred to the usual method of examination is presumed to be the thin-film method. (2) The bulk of available literature refers to quinine treatment carried out amongst civilians reasonably fed and acclimatised and for the most part protected from mosquitoes, exposure, and fatigue.

The resistant cases in this series were often severe massive infections, frequently of mixed type occurring in non-acclimatised individuals recruited from South Africa; owing to exigencies in warfare in German East Africa they were subjected to severe physical strain and hardship involving exposure to tropical sun and rains and unsuitable or insufficient food. In such cases the therapeutic effects of quinine are more slowly produced.

THE SEXUAL PARASITE OF MALIGNANT SUBTERTIAN MALARIA.

The gametes of subtertian malaria are sausage-shaped bodies, longer than the diameter of a red corpuscle showing pigment aggregated into a clump near the centre. These bodies are commonly known as "crescents" in view of their characteristic appearance. The importance of this phase in the life-history of *P. falciparum* is that its presence in sufficient numbers in the peripheral circulation renders the individual infective and a danger to a community in which malaria-transmitting anopheles are present.

Frequency of crescents in peripheral blood.—Considerable difference of opinion prevails as to the frequency with which crescents are found in malignant tertian infections. Deaderick states that, in his experience,

> "Crescents are very rarely seen in blood obtained from the superficial circulation. They are also infrequent in the experience of Plehn, Stephens, Christophers, Ziemann, Wellmann, Annett, Dutton, Elliott, Kendall, and others."

Craig states that:—

> "It often requires a long and patient search to demonstrate the presence of crescents in the blood of individuals who have suffered from æstivo-autumnal infections, and while I believe that a prolonged search would show crescents in 50 per cent. of such cases, still in the study of several hundred cases I have only been able to demonstrate this form in a little over 33 per cent. Rogers found that crescents were present only in 10 per cent. of the cases he observed in Europe. Mason believes that crescents are more frequently observed in cases of malaria which have been contracted in the tropics, but have returned to temperate regions, and that in the tropics it is much more rare to observe this form of plasmodia."

Craig does not agree with Mason, as he has found that the percentage of cases showing crescents in the tropics is practically the same as in temperate regions.

With regard to the frequency of crescents in the peripheral blood it is necessary to consider the following points: (1) method of examination (thick or thin blood smears); (2) number of consecutive examinations; (3) stage of disease at time of observation (acute, convalescent, or chronic); (4) influence of previous treatment; (5) influence of treatment at time of observation; and (6) defensive mechanism of patient (general health).

The statistical records in regard to crescents available from these investigations refer only to the results of examination of thick blood smears, the average number of consecutive examinations being four in each case, each separate examination taking up a maximum of about five minutes. The treatment laid down for all cases of malaria has been previously noted. The thick film method of examination increases the chances of finding crescents by about 30 times when compared with half an hour's examination of a thin blood film. The original infection in these cases was usually contracted several months previously in German East Africa under active service conditions. During this time quinine prophylaxis was usually carried out, and there was generally a history of repeated attacks necessitating admission to field hospitals. The cases were therefore usually admitted to union hospitals with an acute or subacute attack occurring in a more or less chronic infection associated in the more severe cases with a markedly debilitated condition characterised by anorexia, wasting, shortness of breath, and anæmia. (Tables IX. and X.)

TABLE IX.—*Classification of Cards Showing Crescents During Period in Hospital under Quinine Treatment.*

* Average period of observation 52·4 days.

The production of crescents in sufficient numbers in the peripheral blood to enable their presence to be discovered in a thick film indicates that an environment has been created (usually by quinine treatment) sufficiently unfavourable to menace the existence of the asexual generation, the presence of the sexual parasites being an effort on the part of the parasite to prevent total eradication by transference by means of a mosquito to a more favourable environment. So long as the parasite is able to maintain its numbers by a vegetative cycle this method of propagation is selected and preferred by the organism. This is indicated by the fact that crescents are not found in acute stages or in untreated cases of the disease.

The continuous exhibition of inadequate doses of quinine appears to favour the production of crescents owing to the fact that while an unfavourable environment is produced the dosage of quinine employed does not reduce the crescent-forming "rings" sufficiently to prevent the detection of the crescents produced. The presence of numerous crescents in the blood suggests that the asexual generation has been damaged and reduced but not eradicated. The disappearance of crescents shows that progress has been maintained in reducing the infection.

It will, therefore, be seen that crescent formation occurs in infections resistant to treatment in which the destruction of parasites has been slowly effected. The formation of crescents may be prevented in malignant subtertian infections by vigorous and effective quinine treatment in suitable cases owing to the rapid reduction and destruction of the asexual generation, thereby cutting off the supply of "ring" forms destined to develop into crescents. Crescents do not appear similarly in the peripheral blood in untreated infections or markedly resistant infections inadequately treated owing to the fact that the measures adopted for treatment do not menace the asexual generation or establish an unfavourable environment. The appearance of crescents is not an unfavourable sign in the treatment of malignant subtertian malaria in which "rings" only are present in the finger blood, as it is an indication that the therapeutic measures employed are to some extent effective against the asexual generation. Disappearance of all "ring" forms from the peripheral blood and failure to produce crescents indicates that the infection has been hard hit and so reduced in numbers as to justify a favourable prognosis.

CASES UNDER TREATMENT: TIME OF APPEARANCE OF CRESCENTS IN PERIPHERAL BLOOD.

With regard to the time of appearance of crescents in the blood the results of treatment with varying doses of quinine in cases of malignant subtertian malaria showing at first "rings" only in the peripheral blood are indicated in the following summarised tables:—

TABLE XI.—*Quinine Treatment and Time of Appearance of Crescents in Blood.*

Series. (Daily quinine treatment).	No. of cases.	Days of treatment until appearance of crescents.	Average daily quinine.
10 gr.	26	11	10 gr.
11 gr. to 20 gr. ...	110	11	16 „
21 gr. to 30 gr. ...	164	9	28 „
31 gr. to 45 gr. ...	12	9	39 „
	312	9·5	22 gr.

It will be observed that the time of the appearance of crescents is a shorter period in the case of the larger doses of quinine, but that the average time of appearance of crescents is 9·5 days, with an average daily dose of quinine of 22 gr. The shorter interval suggests that an unfavourable environment was more quickly established in the case of the larger doses of quinine.

DURATION OF CRESCENTS IN PERIPHERAL BLOOD.

The crescent is a form of the malignant subtertian parasite particularly resistant to the action of drugs. Quinine has no obvious direct action on crescents, but indirectly it is the most powerful remedy at present available for ridding the blood of them. Its action in these cases is entirely on the ring forms of the parasite which are controlled, reduced, and destroyed, thereby eliminating the forms of the parasite from which crescents are produced. In one series of 1798 crescent infections in which the average daily quinine administered during the persistence of crescents was 25 grains, the average persistence of crescents in the peripheral blood was 15 days. It is therefore clear that crescent infections are not formidable, and tend to clear up in the ordinary way on adequate quininisation. In cases where quinine is insufficient to control the infection and prevent relapses, as in very debilitated individuals, supplementary treatment with organic arsenic preparations, especially "606," given intravenously, has proved useful in breaking down the resistance of the asexual parasites to the action of quinine. These preparations do not appear to exercise any direct destructive action on crescents. A series of 27 cases was treated with intravenous injections of tartar emetic without any definite action of this preparation on crescents being demonstrable. Tartar emetic also has no influence in preventing relapse in malarial infections.

The following figures indicate that so long as an adequate dosage of quinine is employed no obvious advantage as regards persistence of crescents is gained, in ordinary cases of malignant subtertian malaria in which crescents are present in the finger blood, by the addition of intramuscular injections of soamin or intravenous injections of "606" preparations. It should be noted (see Table XII.) that in 1577 cases treated with an average dose of quinine of 24 gr. daily the crescents persisted in the blood for 15 days for all treatments.

TABLE XII.

No of cases.	Average daily quinine.	Duration of crescents.	Treatment series.	No. of injections per case.
952	25 gr.	15	Quinine only.	—
506	21 „	15	Quinine and inorganic arsenic.	—
56	23 „	16	Quinine and soamin.	3
63	24 „	21	Quinine and "605."	3
1577	24 gr.	15	All treatments.	—

It is therefore clear that the eradication of crescents is satisfactorily secured by the control of the asexual generation of the malarial parasite by adequate quininisation. The same is true of the sexual forms of the benign tertian parasite.

This paper is included in a report by the Director of Medical Services to the Minister of Defence, Union of South Africa, on "Malarial Research in South Africa during the War." Acknowledgments are due to Colonel P. G. Stock, Director of Medical Services, and Colonel G. H. Knapp, Deputy Director of Medical Services, for sympathetic support in sanctioning the necessary arrangements for carrying out malarial researches; to Lieutenant-Colonel Andrew Balfour, and Lieutenant-Colonel J. W. W. Stephens, for valuable criticism and advice; to the commanding officers and medical officers of S.A.M.C. hospitals, and medical officers of S.A.M.C. laboratories, Lieutenant-Colonel G. W. Robertson, Majors Targett-Adams, D. Pullon, J. C. Venniker, Captains Pearson, Impey, Luke, Garrow, and Walker, without whose keenness and coöperation it would not have been possible under war conditions to carry out these researches.

THREE CASES OF
INFLUENZAL PNEUMONIA
WITH SEPTICÆMIA AND EXTENSIVE MEMBRANOUS COLITIS.

BY E. CRONIN LOWE, M.B.E., M.B., B.S. LOND.,
PATHOLOGIST TO SOUTHPORT INFIRMARY; BACTERIOLOGIST TO EYE INFIRMARY, LIVERPOOL; LATE CAPTAIN, N.Z.M.C., AND PATHOLOGIST TO NO. 2 N.Z.G.H.

THE cases here recorded occurred among a series of severe influenzal pneumonia cases during the winter of 1919 at the No. 2 N.Z. General Hospital, Walton-on-Thames. The details of history and of bacteriological and pathological findings are given as fully as possible, because the post-mortem examinations revealed a condition of the alimentary canal which has, as far as I know, not been definitely recorded or frequently observed.

The interest centres about the following points:—

(1) The cases were not in any way associated with one another before or during their illness.

(2) They were all apparently definite respiratory infections in which an initial "influenzal" attack developed a rapidly progressive broncho-pneumonia, becoming markedly septicæmic.

(3) Alimentary symptoms were practically absent in each of the cases, and any marked pathological condition of the gut was not anticipated from the slight clinical symptoms observed.

(4) Vaccinal prophylaxis had not been undertaken, except in one case, where a single dose had been administered five days previously to the commencement of the illness.

(5) Treatment during illness varied in each case. In Case A, two doses of 1/12th gr. corrosive sublimate in 1 c.cm. of saline had been given intravenously on the fifth day before death; some abdominal discomfort was complained of the same night and following day, and seven evacuations occurred during this interval, but there was not any violent intestinal disturbance, and during the last three days semi-normal stools were passed. It was very largely because of interest attaching to several influenzal cases in hospital at the same time, in whom more violent intestinal disturbance had followed the intravenous use of corrosive sublimate, that especial attention was directed to the alimentary condition in this case at the post-mortem examination, for no other case which had received intravenous mercury died. In Case B no mercurial or other intravenous medication was given, and in Case C intravenous corrosive sublimate was not given; a mixture of urotropin 25 per cent. and phenol 1 per cent. in saline, a total dose of 8 c.cm., was given intravenously on three occasions on the fourth and second day before day.

(6) Blood culture was attempted four days before death in Case A only, but proved negative. Cultures made at the post-mortem examination from heart, blood, and spleen gave pure streptococcal cultures in each case; the organisms were also present in direct film examinations from the spleens of Cases A and B.

(7) The pathological condition of the respiratory organs of Cases A and C were practically identical. A patchy broncho-pneumonia, becoming confluent through associated œdematous infiltration of intervening lung tissue, was most marked in the lower lobes of both lungs, extending discretely in the upper lobes. Bronchial secretions were not markedly purulent, but fairly profuse and frothy. The bronchi, trachea, and larynx were deeply injected. These broncho-pneumonic areas caused an obvious dark coarse mottling where they reached the pleural surface, but no obvious pleurisy occurred, nor was there excess of pleural effusion.

Definite hæmorrhagic areas, varying from microscopic sizes to extravasations of about ½ inch across, were irregularly distributed throughout the more intensely infected lower lobes. Film preparations of the bronchiole secretions of the more confluent areas showed the presence of pneumococci, streptococci, and *Micro. catarrhalis*, the two former predominating. A few *B. influenzæ* were present, with *M. catarrhalis* and a smaller proportion of streptococci and pneumococci in the less markedly inflammatory areas. Streptococci (markedly hæmolytic), pneumococci, and a few *B. influenzæ*, as well as *M. catarrhalis*, staphylococci, and *B. proteus*, were obtained by culture from the lung tissue.

Detailed Conditions.

Lungs and pleura:—The lung condition of B differed considerably from those of A and C. In this case, accompanying a less intense broncho-pneumonia of the right lower lobe and a still slighter condition of the left, there was an abscess cavity situated near the lower border of the right upper lobe, about 1¼ inches in diameter, its wall reaching but not perforating the pleura at one point; its cavity was full of pink-coloured pus and masses of necrotic tissue; the wall was ill defined. An extensive pleurisy was associated with this abscess, thick, lightly adherent flakes of purulent exudate covering the whole pleural surface, and a fair amount of purulent fluid being present in the pleural cavity. The left pleura was normal. Smear preparations and cultures made from the pleural fluid indicated pure streptococcal infection, while those from the abscess a mixed infection, in which streptococci largely predominated. In all cases the bronchial and tracheal glands were enlarged, congested, and œdematous, being most marked in B, where evidence of early suppurative change was found in the larger glands.

Heart.—The heart in each case was of normal size, the evidence of disease being only found in the dark congestive state of the muscle walls, some small endothelial hæmorrhages occurring around a more general endothelial injection and a pinkish coloration of the aortic cusps, most evident in A. Pericarditis or excess of pericardial fluid was absent in each case. Blood-smears and cultures were made; in each case streptococci were recovered by culture in A and B, a heavy growth in C sparingly. Film preparations showed the organism present in A only.

Spleen.—The spleen of each case showed the usual signs of an intense septic infection, being slightly enlarged, abnormally pink in colour, soft and friable in consistency. Numerous small hæmorrhages occurred in A, and a single abscess about the size of a pea in B. Smear preparations gave evidence of streptococci in B only, but by culture streptococci were recovered from both A and B.

Kidneys.—The kidneys showed the usual pathology—acute septic infection in each case, more intensely congested in A and C than in B, and by microscopic section showing cloudy swelling, acute parenchymatous degeneration of tubules, and intense congestive glomerulitis in each case. In A especially hæmorrhagic effusions into Bowman's capsules and renal tubules were numerous.

Suprarenals, pancreas, liver, peritoneum.—The suprarenals in B and C were apparently normal; in A they were necrotic and degenerative. The pancreas was normal in each case. The liver showed in each case signs of all parenchymatous changes, being unduly pink in colour and increased in size and weight; Glisson's capsule was tense, the parenchyma bulging at the cut surface and its normal pattern indefinite, these changes being most marked in A. The peritoneum in each case was apparently normal; no excess of peritoneal fluid occurred, and no external evidence of the extensive alimentary condition found later was apparent from a general inspection, except in A, where a dull, congestive coloration of the cæcum and transverse colon first attracted attention.

Alimentary Canal.

Œsophagus and stomach.—The inflammatory changes found present commenced in the œsophagus in A and B, but not in C. Both of these cases showed a deeply injected mucosa, which for the lower 1½ or 2 inches became dark in colour and œdematous. This condition extended into the stomach, the cardiac region being intensely injected in A and besides two small superficial ulcers showed the earliest signs of a minute membranous desquamation of the gastric mucous membrane. This condition was not observed in B or C, in which, however, the mucosa was very definitely injected.

Duodenum, jejunum, ileum.—In the duodenum of A and B there occurred further intense congestion, submucous hæmorrhages, and in the former loss of epithelium from the free edges of several rugæ, but no evidence of the membranous necrosis. In C the duodenum was not affected. The jejunum in all cases was respectively much less affected, small isolated areas of the same submucous injection occurring in A only. In the ileum of A and B the intense congestive condition present in the duodenum was again very evident, and in both cases the final 3 feet of the small bowel was marked by extensive submucous hæmorrhages and patches of necrosis. In C the congestive stage only was present.

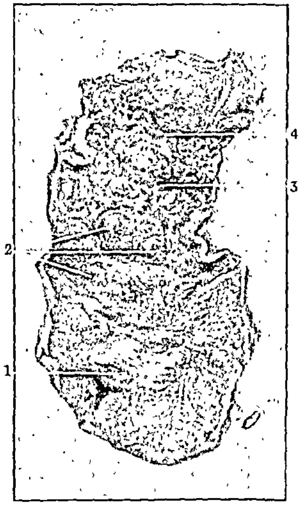

FIG. 1 (Case A).—Cæcum opened out and showing at—1. Ileo-cæcal valve, congested. 2. Three of the many intensely congested and necrotic green lymph follicles, which obviously protrude from the greatly thickened and inflamed mucosa. 3. Area of more intense hæmorrhagic infiltration of mucosa, intensely red and less necrotic. 4. Area of necrotic superficial desquamation.

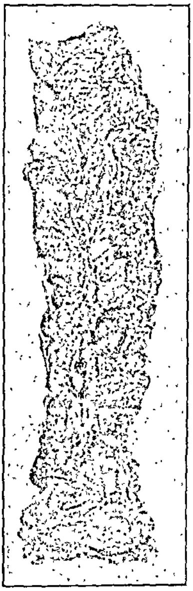

FIG. 2 (Case A).—Transverse colon, showing the condition of necrotic pale-green superficial desquamation, continuous with that of the cæcum and descending colon. The whole submucosa is intensely hæmorrhagic and swollen.

Cæcum.—The cæcum of each case showed the most marked condition. In A practically the whole mucosa consisted of a mass of diphtheritic necrosis of a slate-green colour, with here and there small areas of intense congestion; the lymph follicles were greatly swollen and obvious. This condition extended for 3 to 4 inches up the ascending colon, in which region the necrotic areas were showing some desquamation. There was no definite ulceration, and the appendix, although injected, showed no evidence of necrosis. In Case B the condition was similar to that of A, only of much less degree, while in C there was no evidence of diphtheritic colitis present, but the same intense submucous injection and small hæmorrhages.

Transverse and descending colon.—In each case these portions of the bowel showed a similar picture, but of less intensity and more circumscribed in area. In A the condition extended from the cæcum to within 5 inches of the anus.

This condition of membranous colitis was found in only these three cases who died from influenzal pneumonia. It must be admitted that at previous post-mortem examinations complete investigation of the bowel was not always carried out—the absence of any peritoneal appearance suggestive of such profound colitis having been taken in such cases as sufficient evidence of apparent normality, especially as sufficient reason of cause of death had been demonstrated in the pulmonary lesions found, and in some cases by the source of septicæmic infection by positive blood culture. It is, however, quite possible that some of the earlier cases examined may have also had a similar bowel condition, which was missed by failing to carry out a complete investigation, for until the gut was opened up both B and C, as described above, showed no evidence of the inflammatory changes found.

Conclusion.

A. Abrahams, N. Hallows, and H. French[1] do not describe this condition in their post-mortem findings, and apart from mentioning the fact of the apparent normality of the appendix and bowel generally, do not definitely state whether the bowel was examined in detail throughout. In the Special Report of the Medical Research Council on influenza[2] the intestinal conditions observed were apparently not severe, and, except for the reference to the probability of enteritis being fairly common but that records were not sufficiently kept to give figures on the point (p. 104), the colitis above described is not noted. There is just the possibility that unless the bowel was examined in detail in all cases this condition may have been missed, for one of the features of the condition has been the absence of peritoneal involvement. The acute colitis described in these three cases is, I believe, in keeping with an intensely virulent septicæmic infection, in which profound cytological necrosis may be very rapidly produced; and somewhat similar conditions have been reported to occur in puerperal septicæmia.

I am indebted to my wife for the skilful water-colour drawings from which the illustrations were made.

AMPUTATIONS:

THE EFFECT OF WAR KNOWLEDGE ON TEACHING, PRACTICE, AND AFTER-CARE.

BY EDRED M. CORNER, M.B., M.C. CANTAB., F.R.C.S. ENG.,

MAJOR, R.A.M.C. (T.F.); LATE SURGEON TO THE 5TH LONDON HOSPITAL, KING GEORGE V. HOSPITAL, THE JOHN ELLERMAN HOSPITALS; CONSULTING SURGEON, QUEEN MARY'S AUXILIARY HOSPITAL, ROEHAMPTON; AND SURGEON AND TEACHER OF OPERATIVE SURGERY TO ST. THOMAS'S HOSPITAL.

IN many fields of knowledge the experiences of the recent war have led to considerable change; the latter is, perhaps, more evident in the teaching and practice of such operations as amputations than in any other sphere of medical work. Before the war amputations amongst the civilian population were few and small. Mr. W. Woods, of St. Thomas's Hospital, made me a list of the amputations done there, which made this clear. During the war they have been frequent and have accentuated the fact that the surgeon's work, although the determining factor, was also a bridge to the work of the limb-maker, which has been raised to a higher level of art, with a correspondingly higher level of results and criticism. Our recent knowledge of amputations was derived from the infected cases treated during the war, so that when surgeons returned to civilian practice and relative asepsis it was possible that the old methods would come back, but the instrument-maker has learned that he can get better results after some amputations than in other cases; hence much of our recently gained knowledge has come to stay. This is a great convenience for the student, who will only have to learn about few amputations instead of many.

Amputations of the Lower Limb.

Beginning with leg amputations, from amputations at the metatarso-phalangeal joints to a high Syme above the ankle-joint, all have gone. No longer will student or teacher be bothered with the operations of Lisfranc, Chopart, Pirogoff, Roux, Tripier, Skey, Hey, &c. The high Syme, which gives a very good stump, will remain; the patient will learn to walk well and be nearly as active as he was before. By losing the front of a foot, the patient has lost all spring; moreover, the artificial limb is an unsightly nuisance, the ankle being much broader than the normal ankle and necessitating odd boots and considerable wear of clothing. In some instances the tendo Achillis becomes attached to the scar and tilts the stump forward, making the patient bear on the scar and rendering the stump useless. There are many objections to a stump of a Syme amputation; the foot being largely a passive agent for transmitting pressure, is therefore easily and satisfactorily replaceable, so that the operation is likely to be largely replaced by the easier and more satisfactory one through the middle of the leg.

From accounts given by patients, those who have been amputated through the middle of the leg get along nearly as well as do those who have had a "Syme," whilst they also avoid unsightliness and expensive upkeep. In this amputation the scar must not be terminal; the operation is done with anterior and posterior skin flaps. The former is the larger, making the scar posterior. In this way the amputations of Teale, Hey, and Farabœuf are dispensed with. Ascending the leg, Stephen Smith's operation, together with Price's modification of it, is gone, from useful knowledge and practice. The retention of the patella, as in the operations of Lister, Gritti, and Stokes-Gritti, is not asked for or desired by the limb-maker. Moreover, it has been learned that the patella often becomes loosened and drawn forward by the quadriceps, making the stump and the operation useless. All that remains in the thigh is amputation with anterior and posterior flaps with a posterior scar, like a Carden, but higher up.

Amputation at the Hip.

Perhaps the greatest change has been evolved at the hip joint. Esmarch's modification of Furneaux Jordan's amputation was more widely taught than any other method, but it was soon found to yield a large bulky useless stump, including irregular and new-formed periosteal bone, which had to be re-shaped at a further operation in order to remove all redundant soft tissues defining the pressure points, particularly the tuber ischii, all muscles being cut 1 inch long. The new operation is amply described in Martin Huggins's excellent book on amputation stumps,[1] and is somewhat like the amputation at the hip-joint, advocated by Sir Frederick Treves, surgeon, and Faraboeuf, anatomist. It will suffice here to say that skin flaps are used, and muscles are cut short; by sawing through the neck of the bone the femoral head is left behind, filling the acetabulum instead of leaving a hollow cup behind. It is really an amputation through the neck of the femur by means of an anterior racquet incision. The triradiate scar is anterior, pulling the skin flap tight over the tuber ischii so as to leave it prominent, and giving the limb-maker no excuse for a badly fitting limb. The soft parts are cut so short that they cannot push the artificial limb off the tuber.

Thus of all the many amputations at the hip-joint only one remains. It is usually performed after an amputation of the thigh, to adapt the patient for the work of the fitter. Further, the student has not even to remember any name in connexion with the operation. It may well modify or even replace the second stage in Esmarch's modification of Furneaux Jordan's operation or remain with us as an operation adapting the part for the limb-maker.

It is no use operating less than 3 inches above or below the level of the knee-joint. In the thigh there is an anomaly, the man with a long stump and a long bony lever has to lift a lesser limb and lighter weight than does the man with a short stump and a short bony lever. This is a wrong state of affairs which can only be met at present by supplying the short thigh-stump man with a very light strong artificial limb. If this should prove uncontrollable it can easily be altered. Hence it is no use operating to divide the bone less than 3 inches below the lesser trochanter. Let the amputation be done through the neck of the femur and the man will walk farther, better, and with less aid from a stick.

Amputations of the Upper Limb.

The upper limb is not restricted to weight-bearing; its skilled and active uses have spurred the ingenuity of men in replacing it.

Amputations of the upper limb have been immensely simplified; all forearm amputations are now done with equal anterior and posterior skin-flaps and circular division of muscles and bone. It is no use amputating less than three inches below the elbow. Such an amputation is treated and fitted with an above-elbow artificial limb. Amputations of upper arms are done with a circular incision, which, as it nears the axilla, is met by an internal incision along the vessels, making the circular amputation racquet-shaped. At the shoulder-joint the amputation is carried out similarly. All names are gone. Nothing useful can be fitted to a short upper-arm stump; a long upper-arm stump can be made very useful, and a forearm stump is excellent. It is a very great loss for a man to lose his elbow-joint by re-amputation; the stump should always be considered by surgeon and instrument-maker before anything is done.

Amputations Remaining in Use.

In the lower limb there remain (1) amputations of toes: (2) a Syme's amputation; (3) through leg amputations with skin-flaps; (4) amputations of thigh with long anterior and short posterior flap; and (5) a new amputation through the neck of the femur with skin-flaps. In the upper limb there remain (1) amputations of fingers; (2) amputations of forearm with equal skin-flaps; (3) a circular amputation of upper arm; and (4) Spence's amputation at shoulder.

Linear Amputation: Re-amputation and Excision.

No amputations should leave the limb in its final condition less than 3 inches below or above the elbow- or knee-joints. Amputations through the knee- or elbow-joint have been shown to be inferior to others and are to be discarded. There is another form of operation introduced by Major Fitzmaurice Kelly, R.A.M.C. It was designed to save as much of the limb as possible and to be followed by a further operation, often cinematising in the upper limb, adapting the stump to the fitter, to be performed later under more favourable circumstances. It was simply a flapless through-and-through chop or guillotine amputation. It was used also and independently by the Central Powers and called the "linear amputation." In consequence of this operation and of the almost universal sepsis two other operations have come more into vogue than they ever did before; they have been called re-amputation and excision. Both are measures designed to trim and adapt the stump for the work of the limb-fitter.

---

[1] Oxford Medical Press: Messrs. Frowde, Hodder and Stoughton.

Re-amputation has the great advantage that all nerve-ends and scar tissue are removed completely. Excision of nerve-ends without the whole of the surrounding scar tissue being removed often fails, its smallness and incompleteness accounting for the result. The healing of a wound by primary union, first intention, in no way excludes the presence of micro-organisms in the scar tissue within them. This has been proved by the observations of Dr. L. S. Dudgeon and Lieutenant-Colonel P. W. G. Sargent[2] and later again by Dudgeon.[3] Indeed, a wound that has healed by first intention seems more likely to have irritant infective scar tissue shut up in it than one which has suppurated and been adequately and frankly drained. In fact, drainage in war wounds is the key to their successful treatment. The presence or absence of suppuration is only an indication of the number and character of micro-organisms present in the wound. Local excisions are very likely to be incomplete, too little being removed.

In one case, after a surgeon had very successfully excised some nerves, pain returned, becoming so bad that the suffering man travelled all the way home from Barbadoes; he was unable to wear his artificial leg and had considerable pain night and day. On examination the fibula looked and felt rather longer than the tibia, but a skiagraph showed the apparent elongation of the fibula to be due to the deposit under its end of a substance permeable by X rays. The bone had not been sealed and there was some new-formed bone thrown out near its end. The tenderness, as shown in the patient's own diagram, was in this area; the existence of irritative infective scar tissue under the fibula was diagnosed and the nerves, regenerating, had grown into it. The lower end of the fibula, with the cicatrix, cutaneous and subcutaneous, below it, and with the posterior tibial artery and nerve, were excised through a racquet-shaped incision. The effect was shown at once; pain ceased and pressure over the fibula could be borne. Finally the patient returned to Barbadoes well.

Nerve Regeneration and "Malingering."

During the interval between the amputation and the fitting of the artificial limb the scar tissue in the wound usually becomes non-irritant and non-infective, through the agency of the plasma and lymph. The ordinary cutting short of nerves prolongs this time, as does the injection into them of alcohol, giving the plasma and lymph more chance. But from time to time, as in the case related,[4] the nerves grew, reinfecting the scar tissue by carrying organisms into it, or they re-innervate tissue which has remained infective and irritant, so that pain returns after an interval of comfort. Sleeplessness, drawing, and aching return, and the phantom limb reasserts itself. Patients thus afflicted are in great danger of being regarded as malingerers; indeed, such patients have been submitted to me, and I have learnt again and again that regeneration of nerves into still irritant and infective scar tissue may be responsible for the return of the patient's pain. This danger was illustrated in the case of a soldier sent to me at the 5th London General Hospital, who had had an amputation through the upper leg, just below the knee; later, parts of his internal and external popliteal nerves had been excised higher up, leaving behind the painful bulbs. The nerves regenerated and innervated the still irritant and infective nerve bulbs, with return of the pain and the phantom. The length of the illness depressed the patient and convinced him that he would not recover, and operations did him no good; it is easily comprehensible how he became neurasthenic. His condition deceived his Board, who found that he was a malingerer; but he was not, and after re-excision of the nerves, nerve-bulbs and scar tissue he began slowly to improve—slowly because of his convictions that he would not get better. He did not become well enough to work; his nervous system has never recovered He is useless and miserable. The more operations a man has the deeper is impressed upon his mind the impossibility of recovery. Pain is worse if a nerve is in the proximity of an artery with a silk ligature on it. Such ligatures are better excised, as they or their representatives maintain the irritation, although some of them do no harm. The silk becomes broken into fragments, which are carried away.

Heat, massage, exercise, and like measures bring more blood to the part, quickening the circulation and sterilising the scar tissue, but they act slowly, and the sufferer is usually impatient.

Neurasthenia.

As it is impossible to stop the regeneration of nerves it is necessary to take care that the new fibres do not grow into infective irritative tissue. It is very important in such cases to estimate the degree of neurasthenia present. In almost all cases some degree will be found, for the patients have a hideous past to reflect on, a miserable present to bear, and a dark future to look forward to. The very poverty of our artificial limbs convinces them of their future uselessness. It is sometimes necessary to be very patient before a man can be got to try to help himself. Over such people there must be no differences of opinion. Almost all are neurasthenic, but at the bottom of the neurasthenia is a real cause, however much it may be exaggerated by the patient. It is the duty of those in charge to find that cause, to advise the Ministry of Pensions of it, and not to follow the easy path of regarding all complaints as due to the action of the central or psychological factor.

Conclusion.

For some time we have been conducting experiments with light metal limbs at St. Thomas's Hospital, with the help of Sir Arthur Stanley and the consent of Colonel Webb, Director-General of the Ministry of Pensions. These experiments have been most successful, showing that about 90 per cent. of thigh amputations can advantageously be fitted with light metal limbs, with which the men are able to work with less fatigue and more satisfaction. Moreover, in her excellent instructions Miss Randall showed that men fitted with light metal artificial limbs could be more easily and perfectly instructed in the use of their stumps. They learn more easily. In some cases Dr. Burnett Rae, late of the Cambridge Hospital, Aldershot, and of Millbank, has given most helpful information and treatment by hypnosis. He has done few cases for me, and those the worst, yet they have all permanently improved, and some have become quite well. After-treatment is necessary in most cases—in such a form as return to work without undue delay. Pains and troubles may recur and then they seem to be more definite than they were formerly. Patients should not be kept in hospitals or homes, but should be sent back to work and healthy surroundings.

[3] Horace Dobell Lecture, R.C.P., 1908.

[4] Dr. Urquhart of St. Thomas's Hospital has shown that regenerating nerves can carry organisms with them. Months before this it was known that they carried down foci of inflammation. These were shown in the Arris and Gale lecture for 1919 before the Royal College of Surgeons of England, and in the illustration, p. 88, in the *Practitioner* of February, 1920, of the section of a regenerative neuroma.

ENCEPHALITIS LETHARGICA IN LANCASHIRE.—The case of a young woman in Bolton suffering from this disease has been reported to the medical officer. Two other cases are under observation in Ashton-under-Lyne, where, during the past 12 months, six cases have occurred, only one ending fatally. None of the Ashton patients has, it is stated, been in contact with one another. The two patients have been under observation for several months.

ADOLESCENT ALBUMINURIA IN RELATION TO LIFE ASSURANCE.*

BY R. HINGSTON FOX, M.D., M.R.C.P. LOND.,
PHYSICIAN TO THE FRIENDS' PROVIDENT AND CENTURY LIFE OFFICE.

WITHIN half a century of Bright's discovery of the connexion between albuminuria and disease of the kidney, observers in several countries had noticed that there were types of albuminuria which did not seem to connote kidney disease. Besides those due to the admixture of secretions from the bladder, glands, or urethra, there were other forms produced by temporary causes, such as pyrexia, pregnancy, severe exercise, the taking of alcohol or of drugs. But apart from all of these albuminuria was found to be common in younger subjects, chiefly children or adolescents, without obvious causation, and leading to no ill-results, at any rate in the immediate future. It was often found in candidates for life assurance, and it has exercised the minds of more than one generation of medical examiners. Much has been written upon the subject, and the present author need not repeat what he wrote in 1906.[1] But we may now ask ourselves whether the advance of knowledge has enabled us to define this form of albuminuria more clearly and what its true nature may be. Questions arise as to (1) its possible relation to arterial blood pressure; (2) any series of observations which have been made on the point; (3) any chemical or physio-chemical change in the blood during the disorder; (4) the possibility of any endocrine influence at work; (5) the tests by which it can be distinguished from other forms of albuminuria; (6) its prognosis and possible predisposition to nephritis. The following notes bear on some of these points.

Many names have been given to this form of albuminuria, none of them quite satisfactory, since they are taken from various symptoms or conditions not always present or denote some hypothesis at present unproved. The two least objectionable terms, in the writer's opinion, are albuminuria of adolescents, and hæmatogenous albuminuria. The former (W. Moxon) alludes to the epoch at which it chiefly occurs; the latter (Sir Nestor Tirard) to its dependence on a state of the blood circulation or of the blood itself, rather than of the kidney, a dependence which has come to receive increasing credence.

Causation.

The principal theories of the causation of albuminuria of adolescents are as follows:—

(1) Some early observers connected it with masturbation.

(2) Mechanical conditions of the circulation have been regarded as its cause (F. W. Pavy and others)—either a low, a high, or a variable arterial blood pressure. The effects of posture support this view. It is well known that the albumin is commonly absent during rest; and in many subjects the action of the heart is habitually unstable, and the response to exertion exaggerated. Puberty, with its augmented nervous and vascular tension, may be contributory (Clement Dukes). The lymphatic temperament or diathesis has also been invoked.[2] Vaso-motor instability has therefore been inferred as a cause. There is also a response to emotion, a sort of blushing of the kidney, in some bashful persons.[3]

(3) The blood itself has been thought to be at fault (Sir Almroth Wright). It has been found deficient in coagulating power; this deficiency has been attributed to disordered calcium metabolism due to rapid growth, especially of the bony system. Such rapid growth has taken place in some subjects; and the characteristic skin condition (urticaria-like tache, chilblains, hæmorrhages, and other concomitants of hypo-coagulable blood are often in evidence. Acting on this theory calcium salts have been administered, and in many cases the albumin has disappeared for the time. Large doses must generally be given for this purpose.

(4) The fault has been laid at the door of the digestive system. Sir James Goodhart, reviewing 200 cases of his own, noted the appearance of the albumin in the after-breakfast hours, a period when phosphates and sugar are apt to be passed. He thought there was a state of surfeit, with subtoxic effects. Mr. H. G. Armstrong, however, with large experience of boys at Wellington College, found the albumin in "chapel-fainters" before breakfast. Rapid growth—over-weights were to under-weights as 3 to 2 —and bolting of the food, were, in Goodhart's view, the two chief causes. Dr. R. Saundby also laid stress on large eating and goutiness.[4]

(5) The lordotic theory has been advanced by some German physicians, who found in some cases an exaggerated lumbar spinal curve.

A Case of Albuminuria of Adolescents.

The following is a description of a well-marked case of this form of albuminuria:—

A student, aged 17 years, was sent to me by his family doctor in 1908 on account of the presence of albumin in his urine. He had a fair family history, but an uncle and great-aunt had had much rheumatic fever; there was a personal history of rheumatism in knee and wrist three years earlier, also of severe measles three months ago, during which the albumin was discovered. He was liable to acute headaches, sometimes with vomiting. He had grown very fast, and was now 6 ft. 1½ in. in height, weighing 12 st. 5¾ lb. in ordinary clothing. The pulse-rate varied greatly, between 70 and 135, being increased unduly on exertion. The radial arteries felt hard, but the arterial tension showed much variation at different times, generally raised on exertion and falling during rest—I cannot usefully give figures because the sphygmomanometer then employed was of an old type. The heart's impulse was situated 2½ inches below the nipple, and was sometimes of a forcible knocking character. The urine was examined many times. That passed in the forenoon always contained a good deal of albumin; on one occasion there was only a whitish cloud on boiling, but at other times about 0·5 per cent. by Esbach's tube. The urine passed in the early morning always contained much less, and once was found quite free from albumin. That passed in the evening varied much, but was never free. The urine was concentrated, s.g. usually 1026–1030, very acid, and contained much urates, deposited on cooling, or on using Simon's test (nitric acid introduced through a pipette under the column of urine), when the whole column was filled with the dense mass of urates. Crystals of uric acid were also deposited, and under the microscope some crystals of triple phosphate and calcium oxalate were seen, with mucus cells, an occasional red blood disc, squamous epithelium and cylindroids, but no casts. The coagulability of the blood was tested by Sir Almroth Wright's method, and found apparently deficient. A small proportion of the albumin was thrown down by saturating the urine with magnesium sulphate in the cold, and was therefore judged to be globulin. Mr. Devereux Marshall reported that the vessels of the fundi were quite normal, and in all other respects the patient appeared to be in excellent health. Calcium lactate was given, but in doses not exceeding 30 gr.; it appeared to diminish the amount of albumin. Had it been administered in larger doses it might have had a fuller effect. The patient was advised to leave his studies, and spend six months in open-air work in the country. He did very well, and is now, 12 years later, aged nearly 30 years, said to be in excellent health, an athlete, and engaged in physical training.

In this case the conditions often found in adolescent albuminuria were present in a marked degree. He had both the circulatory instability, with great variability of heart-rate and arterial tension, on the one hand, with the rapid bodily growth and hypocoagulable blood on the other. The albuminuria was considerable in degree and not easily controlled either by rest or by calcium lactate.

Diagnosis.

The diagnosis of this form of albuminuria rests on the following points:—

1. The age is juvenile or adolescent and the general health is good, but the temperament is most often neurotic. There is a form of senile albuminuria which appears to be harmless, but that is not now in question.

2. None other of the signs of kidney disease are present, such as dropsy, hypertrophied heart, continuous high arterial tension, habitual headache, or dyspepsia.

3. The albumin present is not in large quantity (say, under 1 per cent.), and it is absent, or at all events diminished to a very small quantity, in the urine passed after the night's rest.

The above are submitted as the three leading diagnostic tests. The following are confirmatory conditions, but are not in all cases uniformly present.

---

[2] See note by the author, THE LANCET, 1907, i., 1456.

[3] See the author's paper, Trans. L.A.M.O.A., loc. cit.

[4] Discussion in Proc. Roy. Soc. Med., iv., Sect. Med., p. 123.

4. The urine is generally acid to excess, depositing a dense mass of urates when nitric acid is introduced beneath a column of urine. Numerous crystals of calcium oxalate are often formed on standing.

5. There are neither renal cells nor blood cells in the urinary sediment, nor any casts, except, perhaps, a few of the hyaline kind.

6. The albumin contains a larger proportion of globulin than is found in the albuminuria of kidney disease.[5]

7. The passing of albumin is generally stopped for the time by the free administration of calcium salts, say one drachm of the lactate on three successive nights.

8. The arterial blood pressure is usually low, and almost always varies much with slight causes. The pulse is often quickened and the heart's action excitable. Sir W. Broadbent found the right ventricle beating powerfully, whilst the left acted weakly.[6] A history of fainting attacks is not uncommon.

9. The coagulation index of the blood is lowered, with signs of increased transudation.

10. In many cases there has been rapid bodily growth.

It would be of importance if we could add a test to measure the efficiency of the kidneys. A good many such tests are on their trial, based on the output of water, of urea, of diastase, or of salts, or on the removal of indigo-carmine or other substances from the blood.[7] But none of these are yet available for clinical use in the examiner's room. Sir Almroth Wright and Dr. G. W. Ross, of Toronto, published in 1905 a method of estimating renal function by determining the salt-concentration of the urine. They found that the efficiency so estimated continued normal in this form of albuminuria.[8]

Prognosis.

The prognosis of this form of albuminuria is of especial interest to us. The lapse of time since the disorder was first recognised should surely provide data for forming conclusions. Unfortunately few observers keep complete records, and they must needs for our purpose cover many years; impressions and incomplete histories are of but little value. Some data may, however, be put forward.

(1) Dr. Clement Dukes, whose observations on numerous Rugby scholars led him to recognise the disorder as long ago as 1878, is convinced that there is "little likelihood of its proving the precursor of organic disease of the kidneys." In a number of instances Dr. Dukes examined the urine of the same persons in after years. In all cases except one, he tells us, he found it free from albumin; the exception was in a case examined shortly after leaving school.[9]

(2) Sir J. Goodhart noted the after-history in 38 cases, in most of them for over five years. None of them had passed on into Bright's disease, but the period of observation was short.[10] Dr. R. Saundby recorded a like experience with 24 cases, the period ranging from 6 to 13 years.[11]

(3) Dr. Hugh Maclean has reported on the percentage occurrence of albuminuria among 50,000 (healthy) soldiers in France and 10,000 recruits at Aldershot. These reports deal with a large area of statistics, and, being drawn up with much exactitude, will probably become classical of their kind. Albuminuria was found in 5 per cent.; in 2 per cent. "gross albuminuria," and in the remaining 3 per cent. traces of albumin only. Military training was found to have no influence in producing this albuminuria. Of those who were subsequently attacked with war nephritis, the great majority had not shown albuminuria earlier. "Previous albuminuria," Dr. Maclean concludes, "plays little or no part in the ætiology of war nephritis." This is valuable evidence. If the adolescent albuminuria were due to kidney injury, it would surely predispose to nephritis, but it is clear that at any rate war nephritis is not promoted by it.[12]

Summary of After-history of 20 Cases.

In 1906 I submitted a schedule[13] showing the after-history of 19 cases in whom I had found albuminuria of this type when examined for life assurance. The albumin was detected by boiling the acidulated urine, and when only a trace was present this was neglected. Adding a further case, I can now give a summary account of 20 consecutive cases of albuminuria of adolescents, examined between 1884 and 1896. Their average age on entry was 27·7 years. Of the 20, 5 have died: (1) after 7 years, of phthisis; (2) after 7 years, of accident; (3) after 25 years (at the age of 75 years), of senile decay and cardiac failure following accident; (4) after 19 years, of phthisis, in an asylum; (5) after 32 years (at the age of 59 years), of chronic arthritis. Two others were last heard of at periods of 16 and 15 years after entry. They were then living, aged 50 and 48, and believed to be healthy. Of the remaining 13 (two-thirds of the whole number) I have been able to obtain information to the present time. They are all living. The average period since the albuminuria was discovered in these 13 cases is 30 years; their average age is now 56 years, and they are all so far as known healthy persons. No evidence appears from the after-history of these cases, prolonged in some of them for more than 30 years, of any subsequent kidney trouble. The numbers are small, but the notes and histories have been carefully and accurately kept, and the results are now placed upon record as a contribution to the prognosis of this form of albuminuria.

Eligibility for Life Assurance.

If the adolescent type of albuminuria is clearly indicated and the life is in all other respects a healthy one, I would accept it at ordinary rates for an endowment policy payable in 25 years. For a whole-life policy a small advance would in most cases be imposed. If the conditions in any respect fail to reach the first-class standard an advance would be advisable, whatever the form of policy. For although the evidence points, in my view, decisively to the harmless nature of this form of albuminuria, one must regard the general opinion of life office examiners, who have not yet reached this position; and one must give the office the benefit of a cautious estimate.

A Hypothesis of Pathology.

I should like, in conclusion, to try to state a working hypothesis of the pathology of this form of albuminuria. Perhaps we may get some light upon it by approaching the subject from another side. Why does not the colloid albumin of the blood always pass through the walls of the blood-vessels of the kidney into the urine, as it passes through those of the pancreas into the juice of that organ? Urea passes through, and uric acid, pigments, and salts; why not dextrose and albumin? Moreover, if egg albumin is injected into the blood it passes out into the urine; not so serum albumin. Why is one taken and another left?[14] Physiologists can only tell us that such selective action is commonly associated with living cells. The epithelial cells of the glomerulus have a secretory action as to urea and a defensive action as to albumin; but how it is done we do not know.

We may then inquire as to what causes may disturb the defensive action of the epithelial cells of the kidney towards albumin and lead to its passing into the urine. First, the cells may be diseased. In nephritis we see the cells, granular and degenerate, cast off into the urine, and albumin comes with them, no longer retained by the defensive mechanism. Then, in the second place, are there any conditions apart from the healthiness of the cells which may disturb their defensive action? Two such conditions may be suggested. One is the tension of the blood in the capillaries. It is reasonable to suppose that the cells can only work normally when the blood tension is within certain limits, and that a very high or a very low blood pressure may interfere with the defensive mechanism and lead to the passage of albumin. If, then, the vaso-motor control of the arteries of the kidney is disturbed, so that a much higher or lower tension is produced in the capillaries, the cell functions may be impaired. Another condition of the efficient action of the cells may be the integrity of the blood itself. On this much more light is needed, but the suggestion may be made that in hypocoagulable states of the blood—associated with deficiency of calcium salts—the colloid albumins, and especially globulin, are much more ready to pass through the vessel walls. Then the defensive mechanism of the cells may fail and albuminuria appear.

[13] Loc. cit.

[14] Stewart, Manual of Physiology, p. 494.

These hypotheses would account for the occurrence of albuminuria in earlier life, from causes connected, not with the kidney, but with the blood and its circulation. A further suggestion may be made. Is it possible that the cells of the kidney epithelium may sometimes, in old age, undergo a senile change, which is not what we commonly understand by nephritis, nor attended by its clinical signs, and that this change may allow albumin to pass through into the urine? This would explain the cases of long-standing senile albuminuria which have been recorded (by the present writer amongst others) in which death eventually occurred from other causes, sometimes at a very advanced age. Some of the cases lately described under the name of "leaky kidneys" appear to be of this class.[15]

A CONSIDERATION OF THE

POST-OPERATIVE MORTALITY OF APPENDICITIS,

ESPECIALLY IN CHILDREN.

BY HERBERT H. BROWN, O.B.E., M.D. LOND., F.R.C.S. ENG.,
SENIOR SURGEON TO THE EAST SUFFOLK AND IPSWICH HOSPITAL.

WITH BACTERIOLOGICAL REPORT OF BLOOD IN A FATAL CASE

BY H. M. CADE, M.R.C.S., L.R.C.P. LOND., D.P.H.,
PATHOLOGIST TO THE EAST SUFFOLK AND IPSWICH HOSPITAL; BACTERIOLOGIST TO THE EAST SUFFOLK COUNTY COUNCIL.

OPERATIONS for appendicitis are a development of the past 30 years, although the condition was recognised and treated by operation a few years earlier; but after 1890 more and more cases were treated by operation, and early in the present century the name of the disease became widely known.

Twenty-five to twenty years ago late operations were the rule and early operations decidedly exceptional. Cases were not diagnosed as readily or as quickly as they are now, and the sufferers were not so easily persuaded to undergo an operation. No doubt many cases died undiagnosed or unoperated on; and a large proportion of operations were for abscesses of many days' duration, which were treated with great success by simple drainage. Cases of general peritoneal infection seldom recovered. It is not altogether surprising that the mortality from appendicitis 20 years ago was barely half the rate at the present day, according to the Registrar-General's returns. At the present day the disease is rarely undiagnosed. Fortunately many cases are discovered at onset, and are submitted to an immediate operation, with the happiest results.

Owing to the advance of surgical knowledge and technique, general peritoneal infection is robbed of much of its terror, and a very considerable proportion of patients with general infection recover. The operation is a very common one; cases are treated almost daily at all large hospitals. Every operating surgeon has had a large experience in these cases, and yet the mortality shows no sign of diminution. Dr. A. M. N. Pringle, medical officer for the borough of Ipswich, has kindly furnished me with the local records and the Registrar-General's report of the mortality from appendicitis in England and Wales from 1901 to 1918, inclusive; the mortality in 1918 was almost double that of 1901.

Another interesting fact is that the period of childhood and early youth is the most dangerous, nearly half the total number of deaths from appendicitis occurring between the ages of 4 and 20. Of course, it may be argued that the number of cases suffering from appendicitis has increased in an equal or even greater proportion during this period; but, as appendicitis is unfortunately not a notifiable disease, it is not possible to verify this. Certainly far more cases are diagnosed and operated upon now than was the case even 20 years ago, and I think it may be taken for granted that the figure 2416 represents little more than the post-operative mortality for the year 1918. Very few, if any, practitioners at the present day would not advise operation, and few patients decline to avail themselves of it. Is this large mortality unavoidable?

Advantages of Early Operation.

It is an undoubted fact that an operation during the first 24 hours is practically free from danger, and every operating surgeon is glad to see a case as early as this. The appendix is removed with the poison contained within it, the abdomen closed without a drain, and convalescence is rapid and uneventful. During the second 24 hours often the result is as satisfactory, although, of course, there is some risk that the infection may have spread beyond the appendix wall. It is of supreme importance to the sufferer that the disease should be recognised at the earliest possible moment, and the operation performed without any avoidable delay. Too frequently the patient, or the parents or friends, do not at once realise the gravity of the trouble and send for a doctor. The disease is not easily diagnosed at its commencement, and the doctor may hesitate about sending the case to a hospital or calling in a surgeon until he is convinced of the necessity; very precious hours may thus be lost. The larger number of cases are still operated upon after the ideal time has gone, and when the infection has already spread beyond the appendix; there is then peritoneal suppuration, either localised or general.

The increased risk of operation, especially upon children, during the first week, after the time of election has passed—*i.e.*, during the third, fourth, fifth, and sixth days—is, I think, recognised by a good many surgeons. Figures given at an interesting discussion at the Medical Society of London some years ago showed that the death-rate rose rapidly at this time from 2 per cent. on the first day, 2·8 per cent. on the second, to 19 per cent. on the fifth and 22·7 per cent. on the sixth, subsequently falling to 8 per cent. on the seventh and 7 per cent. on the eighth day, and thereafter continuing to fall. An operation during the second week, which usually consists in opening and draining a fairly large abscess, is attended by little danger.

Deaths Due to Infection of Blood During Operation.

Some ten years ago it was my misfortune to lose several cases of children who were operated on during the fifth or sixth days of the disease. The cases were all very similar, treated in the same way, and died with the same symptoms. In each case there was a localised abscess well shut off from the general peritoneal cavity, and in each the condition appeared satisfactory at the time of operation. The abscess was opened, after carefully packing off the peritoneal cavity with gauze, if this had to be crossed, the pus as it escaped carefully mopped up, the abscess cavity swabbed out with gauze till all pus had been removed, a drainage-tube and gauze wick left in the cavity, and the wound closed around the drain. At first the patient appeared to be doing well, but after a definite incubation period, generally about 24 hours, a serious change took place. The pulse became rapid, the face pallid, expression anxious, sometimes there was a rise of temperature, but sometimes it became subnormal; drowsiness with intervals of restlessness and, perhaps, delirium, followed, with an occasional shrill "meningeal" cry; the pupils became dilated and irresponsive to light, and death followed in a few hours. Post mortem nothing could be found. There was no peritonitis, no pus, and only a little serum in the abscess cavity.

What was the cause of death? It was certainly not due to shock or delayed chloroform poisoning. I have no doubt whatever that it was due to the direct infection of the blood at the time of operation.

---

[15] Mackenzie Wallis, loc. cit.

Defence against Infection Outside the Appendix.

A localised abscess is the result of natural effort to fight the infection. In some cases the disease is thus overcome without surgical interference, although at the present day a case is not often left to chance in this way. There are two main walls of defence set up when the infection has passed beyond the appendix to prevent the lethal germs becoming active in the blood. The outer wall is the layer of plastic lymph which is rapidly thrown out from the surrounding tissues, sealing off the general peritoneal cavity and preventing the rapid diffusion of the infected pus through the abdomen. But it also sets up a barrier against invasion of the blood and lymphatic vessels in the omentum, intestine, &c., which form the abscess wall. The layer of lymph lining the abscess acts like the porcelain of a Berkefeld filter, allowing fluid toxins to pass through into the circulation, but holding up the living particulate organisms, bacilli and streptococci, and preventing their entrance into the blood stream. This wall, often lightly disregarded, is in reality of the greatest importance. In course of time the toxins which have entered the blood, bringing about a rise of temperature and pulse and febrile symptoms, cause the development of antibodies which gradually neutralise them, until some time during the second week a condition of equilibrium may be established in the blood and the temperature and pulse may fall to normal. The abscess has "ripened," to use an obsolete term, and a condition of comparative immunity brought about. An operation during this stage is almost free from danger. In the opening of such an abscess fœtid pus with the characteristic odour may flow over the wound in the abdominal wall, which may be sutured round a drainage-tube, and may heal without redness practically by first intention. This is the second wall of defence, taking a week or more to build.

I conclude that in the fatal cases mentioned above by swabbing out the abscess cavity I removed some portion of the protective layer of lymph, thus damaging or destroying the first means of defence, and that owing to the early date, the fifth or sixth day of the disease, the second means—the antibody protection—had not been built up, and that a direct infection of the blood with some of the lethal organism, probably the *Streptococcus fæcalis*, occurred. After a short incubation period the symptoms of a severe blood infection declared themselves. I brought forward this theory in an article[1] published in 1910. I am now in a position to supply what I believe to be a proof of its accuracy.

A child, aged 10, was admitted to the East Suffolk and Ipswich Hospital at 3 P.M. on Oct. 10th suffering from appendicitis. The illness commenced on the morning of the 8th with pain in appendix region, followed by vomiting. Temperature on admission 100° F., pulse 108, condition good. There was a small tender lump in the right iliac region, obviously an inflamed appendix. It was decided to operate at once. The abdomen being opened at the edge of the rectus the appendix at once came into view. It was acutely inflamed, curled on itself, and adherent to cæcum and meso-appendix. The adhesion was firm, evidently due to a previous attack; the appendix was dissected off and removed. The meso-appendix was much inflamed and thickened; a small quantity of pus, about half a drachm, escaped during the separation and was at once mopped up. A clean area was left, which was swabbed out with weak carbolic lotion, a drainage-tube and gauze wick impregnated with bipp introduced, and the rest of the wound closed. On the following day, the 11th, the child appeared to be doing well; temperature 98°, pulse 108. She had slept well during the night.

On the 12th she did not seem quite so well; temperature 97°, pulse 120, abdomen normal, drain removed. On the 13th she had had a restless night, with vomiting; bowels acted. She was drowsy during the day, and at 6 P.M. was evidently much worse; restless, screaming at intervals, with pupils widely dilated. Pulse 140; expression anxious. Some blood was drawn from the basilic vein and one pint of normal saline with bicarbonate of soda introduced. Temperature 97°. The child was very restless all night, pulse becoming more rapid and feeble; death took place at 4 A.M. on the 14th, three and a half days after the operation. The blood was given to Mr. Cade, bacteriologist to the hospital, for bacteriological examination. A streptococcus grew readily in the cultures and was proved by various tests to be *Streptococcus fæcalis*.

The clinical symptoms in this case were identical with those of the cases previously described, and were proved to be due to the invasion of the blood stream by the *Streptococcus fæcalis*—there was nothing else to account for them—which no doubt gained entrance to the blood during the removal of the inflamed and adherent appendix. I think it may reasonably be concluded that the other cases which I have mentioned, in which the symptoms were identical, died from the same cause.

Conclusions as to Treatment.

What conclusions are we to draw to guide us in our treatment? There will be general agreement as to the great importance of operation at the earliest possible moment after the commencement of the attack, preferably during the first 24 hours, while the infection is confined within the appendix. But when the patient, a child, is seen for the first time by the surgeon during the third, fourth, fifth, or sixth days, when the infection has spread beyond the appendix and a localised abscess is formed, the alternatives are immediate operation or delay until the second week (when there is considerable immunity to blood infection).

I cannot help thinking that the safer, though certainly not the easier, course is to wait, although if anything untoward results the surgeon will probably be blamed for his Fabian tactics. Appendix abscesses very rarely burst into the peritoneal cavity if the patient is kept at rest in bed, on a scanty and easily absorbable diet, and the bowels are not disturbed by aperients. During the second week the abscess may be opened and drained with the minimum of danger. But if it is decided to operate at once during the dangerous period I think it is absolutely essential that nothing but the introduction of a drainage-tube into the abscess cavity should be attempted with no swabbing, no handling, no interference of any kind, and, above all, no removal of the appendix. The latter may be safely done many weeks later when all infection has subsided. The great danger of blood infection occurs especially in children; adults appear to have a far greater power of resistance, but to them, too, the same rule should apply.

In cases where there is general peritoneal infection, when the appendix is perforated or gangrenous and free in the abdominal cavity, I think it should always be removed with as little disturbance as possible, and free drainage to the bottom of the pouch of Douglas with a large drainage-tube provided. Of course, with the Fowler position I should not think it justifiable in such case to delay operation, at whatever stage of the disease the patient is seen.

Bacteriological Report of Examination of Blood in a Fatal Case by H. M. CADE.

Varying amounts of blood were inseminated in nutrient bouillon and a taurocholate of soda broth. After 48 hours' incubation at 37° C. these were found to contain a pure culture of a short-chained streptococcus. Subcultures were made on agar, blood-agar, and gelatin. After 48 hours' incubation examination showed a pure culture of the organism. In order to determine, as far as possible, into which group of streptococcus this organism could be relegated, its fermentative reactions were tested on various sugars in peptone water and the following results obtained: Acid formation in lactose, glucose, saccharose, and mannite; no change in inulin. Litmus milk was clotted with the formation of acid and neutral red reduced. No hæmolysis was observed in the blood-agar cultures. A white mouse was inoculated with 1 c.cm. of the 48 hours' broth culture; the organism was non-pathogenic to this animal. Whilst admitting that various strains of streptococci show variability in fermentative reactions, especially when old cultures are used, I am of opinion that, taking into consideration the fact that all the tests were made with fresh cultures, together with the morphology of the organism, its non-hæmolytic power and non-pathogenicity to the white mouse, it should be grouped as a *Streptococcus fæcalis*.

TWO UNUSUAL CASES OF SMALL INTESTINE OBSTRUCTION.

By W. H. OGILVIE, M.A., M.Ch. Oxon., F.R.C.S. Eng.,
SURGICAL REGISTRAR, TUTOR, AND DEMONSTRATOR OF PHYSIOLOGY, GUY'S HOSPITAL.

Strangulation by a Band, with Absence of any of the Usual Symptoms on Admission.

In most surgical cases the history, the patient's symptoms and the objective signs combine to build up a picture on which a diagnosis may be founded and treatment decided upon. In the following case I had to decide whether to trust my eyes or ears, to explore the abdomen on the history alone in face of the clinical findings, or to trust the latter and mistrust the history. I wrongly chose the latter course. Three things influenced me in this decision: first, that I did not know the patient, and had no confirmation of his story from a medical man; secondly, that the passage of flatus as well as fæces is very unusual in any obstruction other than that of a Richter's hernia; thirdly, that the man was a plumber, and since he had very good teeth he might be suffering from lead colic without showing the characteristic blue line on the gums.

CASE 1.—R. H., aged 23, a male, was admitted into Guy's Hospital with a typical history of acute obstruction of the small intestine of three days' duration.

History.—The illness started at 4 P.M. on Oct. 20th with a sudden agonising pain following on three days of vague discomfort. From this time onwards he had been in continual pain, though not so severe. He had vomited such fluids as he had taken by mouth, and had passed nothing per rectum. Further inquiry showed that he had only vomited after food, and that the vomit had never smelt fæcal.

Examination.—On admission he looked well and comfortable, with a clear complexion, and clean moist tongue. Temperature was 100° F., pulse 88, respirations 20. The abdomen was slightly full, but moved well, and there were no distended coils or visible peristalsis. The abdominal muscles were "on guard," but allowed deep palpation if his attention was distracted. There was no definite tender spot, only a vague tenderness to the left of the umbilicus. On rectal examination masses of scybala were felt, but there was no tenderness whatever and no ballooning.

The findings appeared to contradict the history, and a soap-and-water enema was therefore given, and a half-hourly pulse taken. After the enema he passed a large formed motion, with flatus. The pain was relieved and he went to sleep. Next morning (24th) he woke feeling very well, and his pulse was now 68, temperature 98·4°. There was no pain, and only slight tenderness. He remained like this till midday, Oct. 25th, taking fluids with no vomiting, his temperature remaining normal and pulse below 80. At midday, however, his abdomen was definitely more distended, and he did not look so well, though he felt quite comfortable.

Operation (on the 25th).—Laparotomy through a left paramedian incision. Moderately distended coils of small intestine were seen, and the general peritoneal cavity contained a little blood-stained fluid. On passing the hand downwards a band was felt at the pelvic brim passing from right to left, which snapped while being palpated. A mass was felt in the pelvis and brought into the wound, where it was seen to consist of several coils of intestine matted together and surrounding a loop of the lower ileum about 5 inches long, which was gangrenous and greenish-yellow in colour; 12 inches of bowel were resected and a lateral anastomosis performed. The abdomen was closed without drainage. Following the operation recovery was uneventful, and he was discharged perfectly well on Nov. 28th.

Remarks.

The passage of flatus was probably due to bacterial action on the fairly abundant contents of the large gut distal to the obstruction. The absence of any tenderness probably means that the gut had become absolutely gangrenous just before admission, and the same pathology would account for the cessation of the pain and of the vomiting, which in such cases is at first a reflex act, and only later a back-flow due to obstruction. When the bowel became dead painful and reflex stimuli would cease. Had the patient been examined earlier he would probably have been exquisitely tender per rectum. It is very hard to account for the complete absence of vomiting or of any rise of pulse-rate during the next two days, the fourth and fifth of a complete obstruction in the ileum.

With regard to the operation, the choice lay between resection and drainage of the upper ileum by anastomosis to the transverse colon, end-to-end suture, and lateral anastomosis. The good condition of the upper segment rendered the first procedure unnecessary. End-to-end suture is, I think, the operation of choice when dealing with resection of portions of a perfectly healthy intestine, as in gunshot wounds of the abdomen. It is rapid, and gives an almost perfect anatomical restoration. Where the intestine to be resected is in a less healthy condition as in this case, and the reparative powers reduced, one has to be very careful that no leakage can occur at the junction. If end-to-end suture is done with ample invagination of the suture line, drainage of the upper segment is inadequate at the time, and there is a real risk of a stricture at the line of juncture later. With lateral anastomosis a wide opening can be made, and at the same time the sutured edges can be well turned in; the line of junction is further protected by the surrounding coils of intestine.

Reduction "En Masse" of an Inguinal Hernia: Strangulation in the Reduced Sac Six Months Later.

With regard to Case 2, I can only trace two reports of similar cases, one by G. A. Harrison,[1] the other by W. J. Walsham[2]; the latter reports seven cases in all, but in only one case is it clear that the reduction en masse occurred some time before the strangulation for which operation was performed.

CASE 2.—A man of 73 was admitted into Guy's Hospital on the night of Nov. 23rd, with a history of acute obstruction of two and a half days' duration. He was wearing a double inguinal truss.

History.—He said he had had a left inguinal hernia since a young man, for which he had worn a truss. Following a fall at the age of 45 (28 years ago), the hernia became irreducible, but was replaced by manipulation at St. Thomas's Hospital. During the following years the hernia came down frequently, but was always reduced, though often with considerable difficulty. Finally, six months ago, the left inguinal hernia came down into the scrotum, became fixed, and was very tender. He worked at the swelling himself, applying fomentations, and trying various manipulations, and after two hours of these attempts, it went back suddenly into the abdomen, and had never since appeared.

Three days before admission he felt vague abdominal discomfort, but slept well and passed a normal motion next morning. During midday dinner on the 21st he complained of pains in the epigastrium, and at 5 P.M. he commenced to vomit. Next day the abdominal pain was very acute, and the vomiting continued all that day and the next (the 23rd), when, however, the abdominal pain was easier. From the onset of pain on the 21st till admission nothing was passed per rectum, in spite of two enemas.

Condition on admission.—The patient was a stout, well-built old man, but very collapsed. The pulse was 90; temperature under 95° F. He was vomiting frequently, bringing up a brownish fluid with a fæcal smell. The abdomen was not distended, moved well, and was nowhere tender. Both inguinal and femoral canals were empty and not tender at all. Per rectum there was no ballooning of the walls and no fæcal matter; the prostate was large and hard. In view of the extreme collapse, continual vomiting, and absence of distension an obstruction of the jejunum was diagnosed, the most probable cause, in view of the history, being thought to be a band of omentum adhering to the neck of an old left inguinal sac. He was warmed in bed for an hour and then taken to the theatre and given a spinal anæsthetic, but before any incision could be made he was obviously so collapsed that he was returned to the ward, where he died ten minutes later.

Post-mortem.—A very distended jejunum was traced down to the left iliac region, where at a distance of 36 inches from the duodeno-jejunal flexure it entered a peritoneal ring with very hard edges, easily admitting one finger. The emerging gut was narrow and empty. On stripping back the peritoneum this ring was found to lead to a globular sac the size of a large orange, lying between the peritoneum and the transversalis muscle. No part of the sac was in the inguinal canal, but a prolongation upwards of the tunica vaginalis was intimately blended with the fundus of the sac. On pulling the left testis the fundus of the sac was drawn against the internal ring, and conversely on pulling the sac the testis was drawn up against the external ring. This serous process was separable from the sac wall and was a distinct structure. On opening the sac it was found to contain a loop of jejunum 9 inches long, which, though inflamed, was neither adherent nor gangrenous. When the intestine was laid open the walls of the upper jejunum were much hypertrophied, and two constrictions in the wall marked the points of entrance and exit of the obstructed loop, suggesting that it had been in the sac for a considerable period and had suffered partial obstruction for some time. In addition the lower ileum was matted by adhesions into a globular mass not attached to parietes, the cæcum was adherent to the right iliac fossa, and the tip of the appendix was lying free in a very small and short right inguinal sac which barely entered the canal.

---

Remarks.

"Reduction en masse" is frequently described as one of the dangers attending the use of taxis in attempts to return the contents of a strangulated or obstructed hernia into the abdomen. Such "reduction en masse" may be due to replacement of the whole sac and its contents within the abdomen, to displacement of the contents into a lateral diverticulum of the main sac, or to rupture of the sac and replacement of the contents only into the abdomen, leaving the neck of the sac still intact and still causing obstruction or strangulation. Such an accident is nearly always followed by a continuation of the symptoms of intestinal obstruction, leading either to operation or to a fatal result. It must be very rare indeed for reduction en masse to be followed by relief of symptoms, and yet for strangulation to occur at a later period in the sac so displaced. That this is what occurred to this man six months ago when he manipulated his own rupture during an attack of obstruction is, I think, indisputable. The hernia had never been down since, and, as found post mortem, it could not enter the inguinal canal, which would barely admit two fingers. There was no pain or tenderness in the left inguinal region, which seems hard to understand. There is no doubt, however, that had one pulled on the left testis it would have put tension on the sac and caused acute pain, and if a case of this nature were to be seen again it would be a valuable diagnostic sign, and would give one some indication as to where the abdomen should be opened. I intended to make a paraumbilical incision, which in such a fat patient would have needed considerable extension before the point of obstruction could have been reached.

For permission to publish the above cases I am much indebted to Mr. R. P. Rowlands, surgeon to Guy's Hospital.

A NOTE ON

PSYCHOTHERAPY IN GENERAL PRACTICE.[1]

BY W. THOMSON BROWN, *M.C.*, M.B., CH.B. EDIN.

SINCE December, 1919, I have used psychotherapy based on neuro-induction[2] (as opposed to hypnosis or neuro-conduction) in general practice, as far as the requirements of a busy middle- and working-class practice have permitted. I have found it curative in many conditions and also useful in promoting anæsthesia for minor operations, dental extractions, and obstetric cases, as the following instances will show.

I. *Dental Anæsthesia.*

CASE A.—Patient, Mrs. A., has suffered from V.D.H. and auricular fibrillation; also from pyorrhœa alveolaris and dental caries. In March, 1920, I sent her to hospital for extraction of teeth. She fainted in the hospital waiting-room. Her heart was examined and she was recommended for immediate admission. Dental extractions, with or without anæsthetic, were definitely refused as "her heart was too bad." She was told that she might drop dead at any time! She went home and to bed for a week, and feared a sudden death until I disabused her of this notion. On April 24th and 29th I gave her preliminary interviews, suggesting calmness of mind, painless and almost bloodless extractions, and rapid painless healing of the gums, and on the 30th I attended the patient at the dentist's. Twenty-five teeth were extracted in the one sitting. The patient remained placid throughout, except for catching her breath at two specially difficult extractions. When all were out she laughed at the sensation of total absence of teeth. Bleeding stopped immediately, and five minutes later she walked out and left for home. I saw her next day; the gums were very clean, not at all swollen, not at all painful. The minimal pain felt with the two extractions above mentioned amounted to mere discomfort: "I would go through it again any day. I felt I could make a joke of it."

II. *Obstetrics.*

CASE C.—I was called by the nurse to see the patient, Mrs. C., primipara, at 5.50 A.M., on account of her pain, as the nurse had had much difficulty in examining. The patient was slightly deaf (Eustachian catarrh). She allowed me to examine her without fuss. Os not fully dilated, membranes not ruptured. I began induction. The patient complained of "feeling sick." This passed off under suggestion. *After* perfect analgesia was secured I told her it did not matter whether she went to sleep or not, but I suggested that as she had nothing to do she might just as well go to sleep. At 6.15 A.M. the patient was snoring. I left her, promising to return in two hours. At 8.15 A.M. I called again to find the baby had been born at 8.2 A.M., the patient having been perfectly quiet. I expressed the after-birth and left. On my later visit the patient said she remembered relaxation and the pain getting easier and she had heard my talking of going away. She then slept till near the end. She was aware of the last three or four contractions and remembered bearing down for these pains. She described them as violent, but as giving her no sensation of pain. She also felt the head coming out, but had no pain. She had apparently had natural sleep (with, of course, amnesia) for over an hour, analgesia being perfect. The puerperium was normal.

Nervousness in Children.

CASE H.—The parents of this girl, age 10 years, brought her because of her inability to sleep and her troublesome demands on their attention at night. She had defective vision (wore glasses) and had an inherited deformity of pupils. She suffered from visual hallucinations and persisted in "seeing" ghosts, figures on the roof, &c., in spite of parental admonitions to the contrary. She was afraid to be left alone and was frightened of dogs, cats, and mice. Her difficulty in getting off to sleep and her fear of being alone had some relationship with the last phobia. She was impatient, slow to obey, had small powers of attention, and complained frequently of headaches. There being no self-reliance she could not be sent on errands by herself. She was not truthful, and invented complaints to avoid going to school, to escape irksome tasks, or to cover other complaints. She was constipated, and there was marked frequency of micturition at night.

The treatment had in view: (1) training in truthfulness (very important); (2) a rational explanation to the child of her hallucinations; (3) the correction of phobias; (4) the cure of bowel and bladder conditions. I began treatment in the middle of May, 1920, the result being the removal of every symptom complained of. Her school report, July, 1920, states: "...... was hindered by *illness* at the beginning of this term, but she has worked hard during the past six weeks and has gained a much higher place in the class; last March she was near the bottom of the list." That this is not "forcing" but a mere release of mental activity is seen from her mother's statement five months later (October): "Everybody says how different and how well she looks." "A different girl about the house—not the worry she used to be. Is a happy girl now; sleeps well at night. No trouble in any way."

Remarks.

Psychotherapy is still carefully avoided by most general practitioners, partly from a belief that it is too elusive and too far-fetched a subject for the plain man, partly because of its popular association with quackery or with the transcendental psychopathology of the psycho-analysts, and partly from a well-grounded opinion that pecuniary loss or financial ruin would ensue from the use of so-called "hypnotism" in general practice. I wish to emphasise that psychotherapy need have nothing whatever to do with any of these associations and that *anyone* can practise it who cares to acquire the requisite knowledge and learn the technique, qualified medical men only being properly and safely equipped.

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

LEUKÆMIC POLYNEURITIS.

BY WILFRED HARRIS, M.D. CANTAB., F.R.C.P. LOND.,
SENIOR PHYSICIAN, ST. MARY'S HOSPITAL, LONDON.

SEVERE forms of anæmia, cachexia, and senility have been stated occasionally to produce definite multiple neuritis, though the occurrence of well-marked polyneuritis in lymphatic leukæmia has not, so far as I can ascertain, hitherto been recorded. In hæmophilia neuritis has been ascribed to the pressure of the effused blood on nerve trunks, but the resultant neuritis would be local, asymmetrical, and quite unlike the usual form of toxic polyneuritis. Similarly, unilateral facial paralysis has been described in leukæmia.

The case described below illustrates symmetrical polyneuritis as an early and prominent symptom in a case of lymphatic leukæmia, before the definite diagnosis of the blood condition was possible to establish.

W. J., a youth aged 17, attended the out-patient department early in April, 1920, on account of weakness of the legs, saying that for the past five weeks he had noticed that his legs were becoming stiff, followed two weeks later by unsteadiness on his feet, and numbness and tingling of his finger pads. The spleen was noticed to be definitely enlarged, about three fingers-breadth below the costal margin, and the notch easily felt. A slight degree of anæmia was evident, and he was sent into the hospital, being admitted on April 15th. His gait was weak and unsteady, and there was definite weakness of dorsiflexion of the feet, the electrical reaction of the leg muscles showing partial reaction of degeneration. Tests of sensation showed diminution to touch and pin-prick on the feet and legs up to the knees, though the vibration sensation to a large tuning-fork placed on the tibiæ was normal. The knee-jerks, Achilles, and forearm-jerks were all absent, nor could any plantar reflexes be obtained, though the cremaster reflexes were present. Sphincters normal; eyes and discs normal. The blood examination showed a red cell count of 3,400,000, with hæmoglobin content 60 per cent., the colour index being 0·88. There was a degree of leucopenia, the white cells numbering only 5800, though the differential count showed the polymorphs to be reduced to 23 per cent., the lymphocytes amounting to 68 per cent. Wassermann test negative. Numerous small lymphatic glands soon became palpable in the posterior triangles on both sides of his neck, and one of these was removed for microscopical examination. The healing of this wound was very troublesome, recurrent hæmorrhage occurring for several days, and his temperature, which previously had been normal, now began to show oscillations, with rises to 99·5° to 100 F. Gradually he became weaker, and he died on May 29th. Post mortem, the spleen was found considerably enlarged and soft, the liver fatty and weighing 74 oz., while microscopical examination revealed leukæmic infiltration of the liver, nerves, and kidneys, with lymphocytes.

Remarks.

The diagnosis of the case on admission presented a pretty problem. Splenic anæmia with combined sclerosis was negatived by the fact of the absent reflexes, normal vibration sense on the legs, with no involvement of the sphincters, while the clinical picture was indeed characteristic of polyneuritis. The recognition of the type of anæmia was more difficult, the leucopenia being suggestive of splenic anæmia, but the greatly inverted lymphocytic preponderance was against this diagnosis, and was more suggestive of lymphatic leukæmia or lymphadenoma. One of the slightly enlarged glands was therefore excised for microscopical examination, but the pathological report was that it was normal, and again we were at fault. The troublesome hæmorrhage from the small wound in the neck made by the surgeon was more suggestive of leukæmia than of lymphadenoma, but the diagnosis of leukæmia was not established until the tissues were microscoped after the post mortem. The extremely rare combination of well-marked polyneuritis with leukæmia makes it desirable to place this case on record. What exactly is the association between the two conditions is perhaps hard to say. The symmetry of the polyneuritis and its resemblance to many forms of toxic polyneuritis preclude the possibility of the neuritis being due to leukæmic infiltration of the nerves producing paralysis by pressure on the nerve fibres. Clearly it was an instance of toxic degeneration of the peripheral nerves, though, as in so many unexplained forms of "toxic polyneuritis," the source and nature of the toxin remain obscure.

A CASE OF

OPHTHALMIA NEONATORUM BEFORE BIRTH.

BY GRACE H. GIFFEN DUNDAS, F.R.C.S. IREL., D.P.H. CANTAB.,
MEDICAL OFFICER TO MATERNITY AND CHILD WELFARE, MIDDLESBROUGH.

MRS. X., a 2-para, was admitted to the Municipal Maternity Home, Middlesbrough, on Oct. 6th, 1920. Labour pains had commenced ten hours previously. The child was born two hours after the mother was admitted. I saw it within five minutes of its birth, when it was found to have ophthalmia neonatorum. The lids were red and œdematous, and pus was discharging from both eyes. The obstetric sister who conducted the delivery reported the case as left occipito-anterior.

The following history was obtained from the mother:—

Her first child was born healthy; a "creamy discharge" commenced before the second pregnancy and continued during the pregnancy; a fortnight before labour pains set in "the waters began to come away, dribbling all the time," so that the patient was "never dry." The case was evidently one of intra-uterine infection made possible by the draining away of the liquor amnii, and presumably the presentation had been a brow converted into an occipital during labour. Labour pains only lasted 12 hours, but the brow must have been in contact with the infected cervix for some time previous to the commencement of the pains. The mother's puerperium was normal, and she left the home at the end of a fortnight to be treated by her own doctor. The child's eyes received the usual treatment, including hourly saline irrigation, and the discharge began to clear up; intracellular diplococci were demonstrated in the pus. Apart from the eyes the child seemed healthy at birth and weighed 6 lb. 12 oz., but on the third day it began to refuse its feeds, and was slightly cyanosed. The cry was feeble; twitching of the facial muscles occurred several times; the power to suck gradually disappeared, whereupon the child was spoon-fed with the mother's milk. The temperature remained subnormal; the child gradually became more feeble and more cyanosed, and died on the tenth day.

Within 18 hours of the death I received permission to do a limited post-mortem. On removing the calvareum extreme intracranial congestion was found. The sinuses were full of fluid blood, and injection of the pia mater was intense. When the brain was removed a purulent exudate was found on the middle of the base of the skull extending from the optic commissure backwards. There was no disintegration of the globe of either eye. The secondary condition was evidently due to infection by blood or lymph stream.

A CASE OF

AMŒBIC DYSENTERY IN A BOY AGED THREE.

BY M. L. YOUNG, M.B., B.CH. CANTAB.,
HOUSE PHYSICIAN, PADDINGTON GREEN CHILDREN'S HOSPITAL, LONDON.

THE age of the patient and the absence of any obvious source of infection are noteworthy features of this case.

Stanley K., aged 3 years, was admitted to the Paddington Green Children's Hospital on Nov. 3rd, 1920, with the following history. During the six weeks prior to admission he had suffered from persistent diarrhœa, sometimes passing as many as seven stools in the 24 hours, and during the latter four weeks streaks of bright red blood and some slime had been noticed by the mother in almost every stool. Throughout this period of six weeks the boy had been bright and happy, and there had been no complaint of pain or discomfort.

When admitted to the hospital he looked a perfectly healthy and unusually high-spirited boy. During the first 24 hours four loose stools were passed containing a large amount of mucus, well streaked with bright red blood, but very little fæcal matter. Laboratory examination of a stool revealed the presence of the *Entamœba histolytica*, much blood and mucus, and a relatively small amount of pus; no dysentery bacilli were found.

It was then decided to proceed with a course of emetine hydrochloride by hypodermic injection: 1/12th gr. was given on the first occasion, and during the following 24 hours one loose stool was passed containing much mucus but less blood. A second injection of 1/6 gr. was then given, and resulted in further improvement. Two more injections of 1/6th gr. at intervals of 24 hours were given, and a semi-solid partially formed stool was examined and found to contain a considerable quantity of mucus, a few red blood cells, and one or two amœbæ. At this time the diarrhœa was entirely checked. After two further injections of 1/6th gr., at intervals of 24 hours, the child was constipated. Examination of a stool revealed no blood, no amœbæ, and no cysts.

The child was kept under observation in the hospital for another fortnight, and then discharged apparently completely cured. At no time during his stay in hospital did the child appear in the least unwell. The father has never been out of England, and no source of infection has been established. As this is the only case of amœbic dysentery which has been detected at the hospital since the war, it would be interesting to learn the experience of other children's hospitals.

[1] *I am indebted to Dr. G. A. Sutherland for permission to publish the case.*

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A Further Series of 500 Goitre Operations.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 5th, Mr. W. G. SPENCER, the President, being in the chair, when Mr. JAMES BERRY contributed a paper on a Further Series of 500 Goitre Operations, with special reference to the after-results. Numerous charts were exhibited showing the age and sex incidence, the type of tumour, reasons for operation, the lobes affected, the after-results, &c. Many patients were present and a large number of pathological specimens were on view. On the epidiascope were shown photographs of patients, and photographs and coloured drawings of the tumours which had been removed. Of the 500 cases all but 14 had been traced, and Mr. Berry said that from a study of these 14 cases he had no reason to suppose that the after-results were anything but satisfactory. He commented upon the comparatively large number (7 out of 63 men) of men over 70 years of age in his series; there were no women over 70. A large proportion of his cases were women, and this he attributed to the fact that men sought operation only when the tumour was causing discomfort or when it was so enormously large as to produce inconvenience or such unsightliness as would prevent them from getting employment. Women, on the other hand, often came largely for operation for cosmetic reasons, the goitre being usually more in evidence with them than was the case with men.

With regard to the immediate reason for operation, in more than half of the cases of this series (274) operation was performed for dyspnœa. He was anxious to hear opinions as to the suitability of intra-tracheal ether as a mode of anæsthesia for operations of this kind. He urged the importance of the anæsthetic in goitre operations, and said that he never used chloroform but nearly always very light open ether. The intra-tracheal method always seemed to him to be dangerous for just those operations where he would like to use it—namely, cases of extreme dyspnœa with very narrow trachea. So far he had not ventured to try it with goitre operations of this class. In these patients the trachea was so narrowed from pressure by the tumour that its lumen was a mere chink. The deep anæsthesia and extreme extension of the head, both of which appeared to be necessary for the introduction of the tube in intra-tracheal anæsthesia, he thought most dangerous in goitres with extreme suffocative dyspnœa. The pressure of a tube, however soft, in the trachea in contact with the delicate lining of the already narrow trachea, seemed to him not unlikely to produce a dangerous post-operative swelling. For these reasons he had never employed it. On the other hand, it might safely be employed in the less severe cases, but here there seemed no particular advantage in it.

With regard to malignant growths, he urged very strongly that operation should never be performed unless the thyroid not only moved up and down with the trachea, but was also movable on the trachea. He had come across cases where this point had been overlooked and the results had been most disastrous. The patient would probably live only a few weeks after the operation. He also urged on those who were thinking of taking up the surgery of the thyroid gland the importance of a sound and extensive knowledge of its pathological anatomy. The hundreds of specimens in the London museums gave those who lived in London ample opportunity for study.

Mr. Berry demonstrated his method of removing an intrathoracic tumour. Having cleared the tumour around the base of the neck, he levers it up by means of a spoon about the size of a dessert-spoon bent to an angle and thrust through the thoracic inlet and beneath the tumour. At the same time the tumour is pulled from above by means of forceps. Removal of intrathoracic goitres was rendered possible by the fact that, in growing downwards, they carried their vessels with them. In the case of intrathoracic tumours he usually employed light general anæsthesia. If local anæsthesia only were used the patient was apt to move at the most dangerous time—when the tumour was being pulled out of the thorax. Nevertheless, there were certain cases where local anæsthesia alone might be advisable.

Mr. Berry said that he nearly always drained by means of a short glass tube reaching just below the infra-hyoid muscles. This was practically always removed within 24 hours. Of the two deaths which occurred among patients with simple goitre, one was a lady of 38 who had glycosuria. She died of pneumonia ten days after the operation without gross evidence of sepsis. The other case was that of a pregnant woman of 41, on whom the operation was performed on account of dyspnœa. There were 78 patients who had had operation for true exophthalmic goitre (one being operated upon twice) with three deaths, all of which were due to heart failure within a few hours. Among the cases shown was a professional singer, who consulted Mr. Berry because she was losing her voice and thus her means of livelihood. After operation she had regained her voice completely. She demonstrated to the meeting her ability to sing sustained notes.

Discussion and Reply.

In the course of the discussion Sir STCLAIR THOMSON suggested that the word "stridor" should be used instead of "dyspnœa." Stridor was an objective symptom, but dyspnœa was a subjective symptom. In his opinion there were three conditions of stridor which demanded operation—stridor when at rest, stridor when asleep, and stridor on exertion. Fixation of the vocal cord was also an indication for operation, and recovery sometimes followed successful operative treatment. Paralysis of the vocal cord was rarely due to cutting of the recurrent laryngeal nerve. Voice change often came on some weeks after operation, and was probably due to slight suppuration and fibrosis.

Mr. A. J. WALTON gave his opinion as to the indications for operation. Operation should be performed on well-defined adenomata, but if the adenoma was soft and ill-defined, immediate operation was not necessary and the condition often improved under medical treatment. When a goitre was complicated by pregnancy he would always postpone operation until the pregnancy was over, unless the tumour was enormous. In "parenchymatous" goitre there was not a true increase of parenchyma, but much increase of colloid. He preferred to call this type "colloid goitre." Apart from dyspnœa, no colloid goitre should be operated upon, as the condition usually disappeared. Operation should be *performed in cases of extreme dyspnœa.* He said that cases sometimes occurred in which atrophy of cartilage was so great that tracheotomy had to be performed after thyroidectomy. He considered that operation was *the* treatment for exophthalmic goitre of longer standing than about six months. He had seen any permanent benefit from X rays in this dition. He had had 11 cases in which prolonged X treatment had been carried out elsewhere. Two these had squamous carcinoma, and there was scarring in the other cases. None appeared to h benefited. In relapsing cases X ray treatment appeared to be unsuccessful.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

LEUKÆMIC POLYNEURITIS.

BY WILFRED HARRIS, M.D. CANTAB., F.R.C.P. LOND.,
SENIOR PHYSICIAN, ST. MARY'S HOSPITAL, LONDON.

SEVERE forms of anæmia, cachexia, and senility have been stated occasionally to produce definite multiple neuritis, though the occurrence of well-marked polyneuritis in lymphatic leukæmia has not, so far as I can ascertain, hitherto been recorded. In hæmophilia neuritis has been ascribed to the pressure of the effused blood on nerve trunks, but the resultant neuritis would be local, asymmetrical, and quite unlike the usual form of toxic polyneuritis. Similarly, unilateral facial paralysis has been described in leukæmia.

The case described below illustrates symmetrical polyneuritis as an early and prominent symptom in a case of lymphatic leukæmia, before the definite diagnosis of the blood condition was possible to establish.

W. J., a youth aged 17, attended the out-patient department early in April, 1920, on account of weakness of the legs, saying that for the past five weeks he had noticed that his legs were becoming stiff, followed two weeks later by unsteadiness on his feet, and numbness and tingling of his finger pads. The spleen was noticed to be definitely enlarged, about three fingers-breadth below the costal margin, and the notch easily felt. A slight degree of anæmia was evident, and he was sent into the hospital, being admitted on April 15th. His gait was weak and unsteady, and there was definite weakness of dorsiflexion of the feet, the electrical reaction of the leg muscles showing partial reaction of degeneration. Tests of sensation showed diminution to touch and pin-prick on the feet and legs up to the knees, though the vibration sensation to a large tuning-fork placed on the tibiæ was normal. The knee-jerks, Achilles, and forearm-jerks were all absent, nor could any plantar reflexes be obtained, though the cremaster reflexes were present. Sphincters normal; eyes and discs normal. The blood examination showed a red cell count of 3,400,000, with hæmoglobin content 60 per cent., the colour index being 0·88. There was a degree of leucopenia, the white cells numbering only 5800, though the differential count showed the polymorphs to be reduced to 23 per cent., the lymphocytes amounting to 68 per cent. Wassermann test negative. Numerous small lymphatic glands soon became palpable in the posterior triangles on both sides of his neck, and one of these was removed for microscopical examination. The healing of this wound was very troublesome, recurrent hæmorrhage occurring for several days, and his temperature, which previously had been normal, now began to show oscillations, with rises to 99·5° to 100·1° F. Gradually he became weaker, and he died on May 29th. Post mortem, the spleen was found considerably enlarged and soft, the liver fatty and weighing 74 oz., while microscopical examination revealed leukæmic infiltration of the liver, nerves, and kidneys, with lymphocytes.

Remarks.

The diagnosis of the case on admission presented a pretty problem. Splenic anæmia with combined sclerosis was negatived by the fact of the absent reflexes, normal vibration sense on the legs, with no involvement of the sphincters, while the clinical picture was indeed characteristic of polyneuritis. The recognition of the type of anæmia was more difficult, the leucopenia being suggestive of splenic anæmia, but the greatly inverted lymphocytic preponderance was against this diagnosis, and was more suggestive of lymphatic leukæmia or lymphadenoma. One of the slightly enlarged glands was therefore excised for microscopical examination, but the pathological report was that it was normal, and again we were at fault. The troublesome hæmorrhage from the small wound in the neck made by the surgeon was more suggestive of leukæmia than of lymphadenoma, but the diagnosis of leukæmia was not established until the tissues were microscoped after the post mortem. The extremely rare combination of well-marked polyneuritis with leukæmia makes it desirable to place this case on record. What exactly is the association between the two conditions is perhaps hard to say. The symmetry of the polyneuritis and its resemblance to many forms of toxic polyneuritis preclude the possibility of the neuritis being due to leukæmic infiltration of the nerves producing paralysis by pressure on the nerve fibres. Clearly it was an instance of toxic degeneration of the peripheral nerves, though, as in so many unexplained forms of "toxic polyneuritis," the source and nature of the toxin remain obscure.

A CASE OF

OPHTHALMIA NEONATORUM BEFORE BIRTH.

BY GRACE H. GIFFEN DUNDAS, F.R.C.S. IREL., D.P.H. CANTAB.,
MEDICAL OFFICER TO MATERNITY AND CHILD WELFARE, MIDDLESBROUGH.

MRS. X., a 2-para, was admitted to the Municipal Maternity Home, Middlesbrough, on Oct. 6th, 1920. Labour pains had commenced ten hours previously. The child was born two hours after the mother was admitted. I saw it within five minutes of its birth, when it was found to have ophthalmia neonatorum. The lids were red and œdematous, and pus was discharging from both eyes. The obstetric sister who conducted the delivery reported the case as left occipito-anterior.

The following history was obtained from the mother:—

Her first child was born healthy; a "creamy discharge" commenced before the second pregnancy and continued during the pregnancy; a fortnight before labour pains set in "the waters began to come away, dribbling all the time," so that the patient was "never dry." The case was evidently one of intra-uterine infection made possible by the draining away of the liquor amnii, and presumably the presentation had been a brow converted into an occipital during labour. Labour pains only lasted 12 hours, but the brow must have been in contact with the infected cervix for some time previous to the commencement of the pains. The mother's puerperium was normal, and she left the home at the end of a fortnight to be treated by her own doctor. The child's eyes received the usual treatment, including hourly saline irrigation, and the discharge began to clear up; intracellular diplococci were demonstrated in the pus. Apart from the eyes the child seemed healthy at birth and weighed 6 lb. 12 oz., but on the third day it began to refuse its feeds, and was slightly cyanosed. The cry was feeble; twitching of the facial muscles occurred several times; the power to suck gradually disappeared, whereupon the child was spoon-fed with the mother's milk. The temperature remained subnormal; the child gradually became more feeble and more cyanosed, and died on the tenth day.

Within 18 hours of the death I received permission to do a limited post-mortem. On removing the calvareum extreme intracranial congestion was found. The sinuses were full of fluid blood, and injection of the pia mater was intense. When the brain was removed a purulent exudate was found on the middle of the base of the skull extending from the optic commissure backwards. There was no disintegration of the globe of either eye. The secondary condition was evidently due to infection by blood or lymph stream.

A CASE OF

AMŒBIC DYSENTERY IN A BOY AGED THREE.

BY M. L. YOUNG, M.B., B.CH. CANTAB.,
HOUSE PHYSICIAN, PADDINGTON GREEN CHILDREN'S HOSPITAL, LONDON.

THE age of the patient and the absence of any obvious source of infection are noteworthy features of this case.

Stanley K., aged 3 years, was admitted to the Paddington Green Children's Hospital on Nov. 3rd, 1920, with the following history. During the six weeks prior to admission he had suffered from persistent diarrhœa, sometimes passing as many as seven stools in the 24 hours, and during the latter four weeks streaks of bright red blood and some slime had been noticed by the mother in almost every stool. Throughout this period of six weeks the boy had been bright and happy, and there had been no complaint of pain or discomfort.

When admitted to the hospital he looked a perfectly healthy and unusually high-spirited boy. During the first 24 hours four loose stools were passed containing a large amount of mucus, well streaked with bright red blood, but very little fæcal matter. Laboratory examination of a stool revealed the presence of the *Entamœba histolytica*, much blood and mucus, and a relatively small amount of pus; no dysentery bacilli were found.

It was then decided to proceed with a course of emetine hydrochloride by hypodermic injection: 1/12th gr. was given on the first occasion, and during the following 24 hours one loose stool was passed containing much mucus but less blood. A second injection of 1/6 gr. was then given, and resulted in further improvement. Two more injections of 1/6th gr. at intervals of 24 hours were given, and a semi-solid partially formed stool was examined and found to contain a considerable quantity of mucus, a few red blood cells, and one or two amœbæ. At this time the diarrhœa was entirely checked. After two further injections of 1/6th gr., at intervals of 24 hours, the child was constipated. Examination of a stool revealed no blood, no amœbæ, and no cysts.

The child was kept under observation in the hospital for another fortnight, and then discharged apparently completely cured. At no time during his stay in hospital did the child appear in the least unwell. The father has never been out of England, and no source of infection has been established. As this is the only case of amœbic dysentery which has been detected at the hospital since the war, it would be interesting to learn the experience of other children's hospitals.

I am indebted to Dr. G. A. Sutherland for permission to publish the case.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A Further Series of 500 Goitre Operations.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 5th, Mr. W. G. SPENCER, the President, being in the chair, when Mr. JAMES BERRY contributed a paper on a Further Series of 500 Goitre Operations, with special reference to the after-results. Numerous charts were exhibited showing the age and sex incidence, the type of tumour, reasons for operation, the lobes affected, the after-results, &c. Many patients were present and a large number of pathological specimens were on view. On the epidiascope were shown photographs of patients, and photographs and coloured drawings of the tumours which had been removed. Of the 500 cases all but 14 had been traced, and Mr. Berry said that from a study of these 14 cases he had no reason to suppose that the after-results were anything but satisfactory. He commented upon the comparatively large number (7 out of 63 men) of men over 70 years of age in his series; there were no women over 70. A large proportion of his cases were women, and this he attributed to the fact that men sought operation only when the tumour was causing discomfort or when it was so enormously large as to produce inconvenience or such unsightliness as would prevent them from getting employment. Women, on the other hand, often came largely for operation for cosmetic reasons, the goitre being usually more in evidence with them than was the case with men.

With regard to the immediate reason for operation, in more than half of the cases of this series (274) operation was performed for dyspnœa. He was anxious to hear opinions as to the suitability of intra-tracheal ether as a mode of anæsthesia for operations of this kind. He urged the importance of the anæsthetic in goitre operations, and said that he never used chloroform but nearly always very light open ether. The intra-tracheal method always seemed to him to be dangerous for just those operations where he would like to use it—namely, cases of extreme dyspnœa with very narrow trachea. So far he had not ventured to try it with goitre operations of this class. In these patients the trachea was so narrowed from pressure by the tumour that its lumen was a mere chink. The deep anæsthesia and extreme extension of the head, both of which appeared to be necessary for the introduction of the tube in intra-tracheal anæsthesia, he thought most dangerous in goitres with extreme suffocative dyspnœa. The pressure of a tube, however soft, in the trachea in contact with the delicate lining of the already narrow trachea, seemed to him not unlikely to produce a dangerous post-operative swelling. For these reasons he had never employed it. On the other hand, it might safely be employed in the less severe cases, but here there seemed no particular advantage in it.

With regard to malignant growths, he urged very strongly that operation should never be performed unless the thyroid not only moved up and down with the trachea, but was also movable *on* the trachea. He had come across cases where this point had been overlooked and the results had been most disastrous. The patient would probably live only a few weeks after the operation. He also urged on those who were thinking of taking up the surgery of the thyroid gland the importance of a sound and extensive knowledge of its pathological anatomy. The hundreds of specimens in the London museums gave those who lived in London ample opportunity for study.

Mr. Berry demonstrated his method of removing an intrathoracic tumour. Having cleared the tumour around the base of the neck, he levers it up by means of a spoon about the size of a dessert-spoon bent to an angle and thrust through the thoracic inlet and beneath the tumour. At the same time the tumour is pulled from above by means of forceps. Removal of intrathoracic goitres was rendered possible by the fact that, in growing downwards, they carried their vessels with them. In the case of intrathoracic tumours he usually employed light general anæsthesia. If local anæsthesia only were used the patient was apt to move at the most dangerous time—when the tumour was being pulled out of the thorax. Nevertheless, there were certain cases where local anæsthesia alone might be advisable.

Mr. Berry said that he nearly always drained by means of a short glass tube reaching just below the infra-hyoid muscles. This was practically always removed within 24 hours. Of the two deaths which occurred among patients with simple goitre, one was a lady of 38 who had glycosuria. She died of pneumonia ten days after the operation without gross evidence of sepsis. The other case was that of a pregnant woman of 41, on whom the operation was performed on account of dyspnœa. There were 78 patients who had had operation for true exophthalmic goitre (one being operated upon twice) with three deaths, all of which were due to heart failure within a few hours. Among the cases shown was a professional singer, who consulted Mr. Berry because she was losing her voice and thus her means of livelihood. After operation she had regained her voice completely. She demonstrated to the meeting her ability to sing sustained notes.

Discussion and Reply.

In the course of the discussion Sir STCLAIR THOMSON suggested that the word "stridor" should be used instead of "dyspnœa." Stridor was an objective symptom, but dyspnœa was a subjective symptom. In his opinion there were three conditions of stridor which demanded operation—stridor when at rest, stridor when asleep, and stridor on exertion. Fixation of the vocal cord was also an indication for operation, and recovery sometimes followed successful operative treatment. Paralysis of the vocal cord was rarely due to cutting of the recurrent laryngeal nerve. Voice change often came on some weeks after operation, and was probably due to slight suppuration and fibrosis.

Mr. A. J. WALTON gave his opinion as to the indications for operation. Operation should be performed on well-defined adenomata, but if the adenoma was soft and ill-defined, immediate operation was not necessary and the condition often improved under medical treatment. When a goitre was complicated by pregnancy he would always postpone operation until the pregnancy was over, unless the tumour was enormous. In "parenchymatous" goitre there was not a true increase of parenchyma, but much increase of colloid. He preferred to call this type "colloid goitre." Apart from dyspnœa, no colloid goitre should be operated upon, as the condition usually disappeared. Operation should be performed in cases of extreme dyspnœa. He said that cases sometimes occurred in which atrophy of cartilage was so great that tracheotomy had to be performed after thyroidectomy. He considered that operation was *the* treatment for exophthalmic goitre of longer standing than about six months. He had never seen any permanent benefit from X rays in this condition. He had had 11 cases in which prolonged X ray treatment had been carried out elsewhere. Two of these had squamous carcinoma, and there was much scarring in the other cases. None appeared to have benefited. In relapsing cases X ray treatment also appeared to be unsuccessful.

Mr. BERRY said that he only knew of three cases of paralysis of the vocal cord in this series, though there might be others. He thought that X rays had a definite field of usefulness in the cases of early and mild exophthalmic goitre, but it was wrong to continue treatment too long. He had seen cases of mild exophthalmic goitre which had certainly benefited. In answer to a question by the PRESIDENT, Mr. Berry said that he paid no attention whatever to the parathyroid glands. He must have removed them many times, but none of his patients had at any time developed tetany.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

MEDICAL SECTION.

A Case of Bubonic Plague in Dublin.

AT a meeting of this section on Dec. 10th, 1920, Dr. *H. C.* DRURY and Sir ARTHUR BALL reported a case of Bubonic Plague which had occurred in Dublin. The woman, aged 25, was seen by Sir Arthur Ball, who found a gland in the groin the size of a walnut, with a history of intense local pain of three days' duration. On admission her temperature was 104° F. The skin over the gland was not inflamed. The patient was covered with flea-bites. The excised gland was examined by Dr. V. M. Synge who found that it contained large numbers of plague bacilli. When Dr. Drury first saw the case on the third morning after operation, he was struck with her typhus-like aspect. The temperature was then 102°, pulse-rate 100 but very weak, respirations 22. Except for a deep and exquisitely tender swelling, 2½ by 1 in. immediately above and parallel to Poupart's ligament, the abdomen was normal. There was no vesicle or pustule to indicate the site of inoculation. On the sixth day of the disease the temperature began to fall steadily, rising again on the eleventh day to 102°, and becoming definitely normal on the thirteenth day. The swelling above Poupart's ligament gradually subsided.

Discussion.

Dr. J. W. BIGGER, in describing the precautions taken by the authorities to prevent extension of the disease, said that as no case had occurred in Dublin for 200 years an entirely new problem was presented. Some connexion with the shipping of the port might have been expected, but this case had none, except that she lived near the docks. She had, however, a pet cat which slept in her bed and which was in the habit of disappearing at intervals. This animal might have been infected by rat fleas, but it was not possible to ascertain the fact owing to its prompt destruction by the sanitary authorities. No unusual mortality had been noticed among the rats at the docks, and the specimens examined were negative as regards plague. The usual measures of disinfection were adopted, and the health authorities in England and Scotland were notified. As no further case had been reported after the lapse of nearly two months this would probably prove an isolated case.

Dr. W. F. LAW had never seen a case of plague in his colony (B. Guiana), but it had occurred in Trinidad on two occasions to his own knowledge. He was surprised to hear that direct infection played such a prominent part; he thought the rat flea was generally accepted as the infecting agent.

Sir J. W. MOORE thought the introduction of plague into this country quite a possible event. A relative in the Royal Navy had told him on his return home after visiting Algiers and Lisbon that plague existed in Algiers and in Lisbon, both places in fairly close communication with the British Isles.

Dr. J. SPEARES instanced an outbreak in a family in Malta, two members of which died before the diagnosis was made. The laboratory attendant punctured his finger during an autopsy on one of the cases, developed plague, and died.

Dr. SYNGE said that the gland removed by Sir Arthur Ball was about 1½ inches in length. It was œdematous and hæmorrhagic. Smears from the gland showed very large numbers of Gram-negative bacilli. These bacilli were short and thick, and stained darkly at both poles, the centre of the bacillus remaining unstained. Cultures on blood-agar after 36 hours showed small whitish-grey colonies. These consisted of bacilli similar to those found in the direct smears of the gland. Cultures on salt agar after three days showed marked involution forms. A guinea-pig injected with material from the gland died after seven days. It showed general œdema with areas of congestion. The glands in the groin were much enlarged, œdematous, and hæmorrhagic. The spleen was greatly enlarged and studded with large numbers of white spots. Smears of the glands and spleen, and cultures from the glands, spleen, and heart's blood all showed bacilli similar to those found in the patient's gland. A culture from the patient's blood on the seventh day of her illness was positive, but bacilli were not seen in a direct examination of blood films. The morphological and cultural appearances and the result of animal inoculation proved that the bacillus found in the patient's gland was *B. pestis*, and that the patient was suffering from bubonic plague.

Dr. DRURY, in reply, said that the entire credit of the case was due to Sir Arthur Ball, who recognised the inflamed gland as something unusual, and to Dr. Synge, who had the courage to make what appeared at first a very improbable diagnosis. He did not suggest that direct infection in plague was a common route, but it had been shown to occur. He thought anti plague serum more useful in prophylaxis than in treatment.

Acute Leukæmia.

Dr. F. C. PURSER showed blood films of Acute Leukæmia. The child, a male, aged 3 years 2 months, was admitted as a case of acute purpura with temperature of 103° and pulse 138, and died 36 hours after admission. The blood showed 72,812 leucocytes per cubic centimetre of mononuclear type. Hæmoglobin 50 per cent., red cells 2,800,000.

Dr. SPEARES commented on the bluish appearance of the red cells in the films prepared with Leishman's stain, and said this was generally due either to the films having been kept a long time before staining or to the stain not being sufficiently alkaline. On account of the peculiar staining, he found it difficult to pronounce on the character of the white cells, but he considered that the majority were myelocytes, myeloblasts, or metamyelocytes. He thought the case undoubtedly belonged to the myelogenous variety of leukæmia.

Dr. G. E. NESBITT, having seen the case on its admission to hospital, was much interested in the subsequent details. He was struck by the peculiar pallor, the petechial eruption, and the blood-stained oozing from the mouth, which had been present in some form in every case of acute leukæmia he had seen. He thought a bluish tint in the red cells was a common experience, and he did not find that it prevented recognition of the leucocytes, which often seemed to stain unusually well under these conditions. The patient was an exceptionally fine child, and the sudden occurrence of such a profound and mysterious disorder was quite inexplicable.

Dr. R. J. ROWLETTE also often obtained a grey appearance of the red cells with Leishman's stain, but as regards the white he would judge more from their morphology. He thought the blood did not conform to either established type, but as usual in acute cases the cells more closely resembled the large lymphocytes, and this appearance was characteristic of the condition.

Dr. PURSER, in reply, said that Dr. J. H. Pollock had been responsible for most of the work on the case. He agreed that bleeding from the gums was a characteristic feature of acute forms of leukæmia. The stain used was probably bad, but he thought it likely that the alcohol was to blame.

OBSTETRICAL SECTION.

A MEETING of this section was held on Dec. 10th, Dr. E. HASTINGS TWEEDY, the President, in the chair. Dr. BETHEL SOLOMONS read a paper on

Herpes as a Type of Vicarious Menstruation.

He reported a case which had been referred to him by Dr. Wallace Beatty. The patient was a girl, aged 27, who complained of getting a sore on her left cheek every month, which Dr. Beatty described as catarrhal herpes. Bimanual examination under anæsthetic revealed absence of the essential genitalia. It was thought well to confirm this diagnosis, and the abdomen was opened. It was then seen that a candle-like structure passed from one internal abdominal ring to the other, and that the uterus, tubes, and ovaries were absent. On a further search an ovary of normal size was found attached to a very thin fold of peritoneum, which was in such a position that it might have been intended to represent the broad ligament. The ovary was anterior to this. There was no ovarian or ovario-pelvic ligament, and the ovary was obviously obtaining its blood-supply from the peritoneum in which it was nestling. Dr. Solomons, having discussed the question, considered that the case might be ranked as one of vicarious menstruation.

Dr. SPENCER SHEILL said that he agreed with many present-day authorities that vicarious menstruation does not exist. In cases of pink discharge coming monthly from axillæ neither red cells nor hæmatin were found in it. He looked upon herpes as a very common accompaniment of menstruation, just as headaches, swellings, &c., are. These symptoms increase in menstrual derangements, and are merely manifestations of vaso-motor disturbance due to internal ovarian secretion. When periodical hæmorrhages occur—e.g., epistaxis—local causes have invariably been found which, when treated, removed the so-called vicarious menstruation.

Dr. DAVID MADILL asked if any form of pluriglandular extract had been tried in this case.

Mr. A. K. HENRY said that menstruation involved notable vaso-motor changes, and these were controlled by the autonomic nervous system which, taken as a whole, was concerned with widespread reactions. Dermographism, for example, was described as being specially pronounced in certain individuals during menstruation, and it was possible to account for this, and for catamenial herpetic eruptions, by a diffusion of exaggerated vaso-dilator response; or, as in Dr. Solomons's case, by a complete shunting of vaso-motor effects into extra-genital channels. In dermographism urticaria was simulated, while in herpes the results of vaso-motor activity proceeded to the formation of vesicles.

Dr. SOLOMONS, in reply, said that he was one of those who believed that vicarious menstruation did exist. It was open to question as to whether his case was actually an example of the condition. According to Dorland's definition it certainly was. All drug treatments had been tried, and still the herpes recurred every month. He did not remove the ovary, as he thought the absence of its secretion would be more harmful to the girl than the presence of the herpes.

Dr. R. A. MACLAVERTY gave an account of some observations made during a recent American tour.

ULSTER MEDICAL SOCIETY.

A MEETING of this society was held on Jan. 6th, Dr. T. HOUSTON, the President, in the chair.

Hæmaturia: Surgical Aspect.

Mr. A. FULLERTON introduced a discussion on this subject, basing his remarks upon a series of 600 cases, illustrated by lantern demonstrations. The cystoscope, combined in many cases with radiography, was indispensable for the examination of hæmorrhage from kidney, ureter, bladder, or prostate, and the urethroscope for doubtful cases of ureteral hæmorrhage. Its indiscriminate use should, however, be discouraged, as it might prove a dangerous weapon in certain cases of tubercle, malignant disease, sepsis, and incipient or established uræmia. The ordinary methods of examination should first be employed, the cystoscope being used when required. When blood is intimately mixed with the urine it was probable that the source of the hæmorrhage was the kidney, but the rule was not absolute. All that could be said in such cases was that the blood had been shed in small or moderate quantity, allowing of intimate admixture before clotting had taken place. The presence of frequency of micturition was strongly suggestive of the bladder or prostate as the source of the hæmorrhage, but dependence could not be placed upon this rule. Frequency of bleeding in an old man would at once suggest enlarged prostate, but might depend upon papilloma of the bladder or other conditions. When frequency of urination and hæmaturia were combined with pain in the glans penis, scalding, urgency, and the presence of pus and mucus, cystitis was probable, but malignant growths and calculus must be excluded by direct examination. Pain in one lumbar region was sometimes present when the disease was in the opposite side. Initial hæmorrhage pointed to the prostate or the urethra as the seat of the bleeding. Blood issuing from the urethra independent of micturition came from a source distal to the compressor urethra. Hæmaturia with massive clotting was often of bladder origin, but might depend upon wounds or tumours of the kidney. A long cast of the ureter pointed to its origin. Casts formed in the urethra were thicker and often showed constrictions corresponding to those normally present in the canal. Microscopical examination of the urine might give useful information by showing the presence of renal casts, cells from the bladder, ureter, or kidney, portions of tumour, pus cells, crystals, micro-organism, &c. Mr. Fullerton then analysed his own cases as follows:—

Tubercle of the kidney.—Tuberculosis of the urinary tract was common in the North of Ireland, nearly 10 per cent. of his cases of cystoscopy belonging to this category, of which 75 per cent. had hæmaturia. Tuberculosis of the urinary tract usually began in the kidney and was very rarely, if ever, primary in the bladder. The blood usually came from ulcers in the bladder, severe hæmaturia from the kidney being rare.

Symptomless renal hæmaturia.—He had seen 47 cases of renal hæmaturia in which it was the only symptom, the "renal epistaxis" of Gull. The hæmorrhage had been more or less severe and persistent, with intervals of freedom when the urine was normal. The bleeding was unilateral. The patient was otherwise in fair or good health, and the hæmaturia might persist for years without any serious results. Various hypotheses had been put forward with regard to these cases, but the real cause or causes remained obscure. He had seen 44 cases of renal calculus with hæmaturia. Renal colic, hæmaturia, and vomiting were common, but not invariable, in cases of renal calculus. At the present time he would be reluctant to operate without an X ray examination. The symptoms of renal calculus might be closely simulated by tuberculosis of the kidney, new growths, hydronephrosis, the presence of an accessory renal artery, pyonephrosis, hydatid cysts, and ureteral spasm. The most usual cause of pyelitis was the presence of the *B. coli communis*, but streptococci, staphylococci, the *Diplococcus fæcalis*, diphtheroid bacilli, and other organisms might occur. The amount of blood was usually small. Every case of pyelitis should be X rayed. He had seen a patient treated for months by vaccines when the exciting cause proved to be a stone in the pelvis of the kidney.

Renal tumours and cysts.—This group included 21 cases. In congenital cystic kidney the bleeding might be profuse. As this type of tumour was bilateral it was useless to remove one kidney. In some cases of renal tumour the bleeding was very profuse. It might be painless or associated with symptoms of renal colic. He was not sure that every case of renal hæmaturia of doubtful origin should not be explored so as to avoid missing early cases of malignant disease. The appearance of a tumour in the side showed that the disease was in an advanced stage. Radiography might be useful in these cases. Nephritis belonged to the sphere of the physician. Their chief feature, from the cystoscopic point of view, was the presence of blood on both sides. Other signs or symptoms of renal disease, such as the presence of casts in the urine, cardio-vascular changes, albuminuric retinitis, would be found on examination. Hæmaturia was not a cardinal sign of hydronephrosis, but was often present. The chief signs of hydronephrosis were pain, sometimes developing into renal colic with vomiting, a tumour in the lumbar region varying in size from time to time and sometimes disappearing. In 4 cases of pyonephrosis, in 3 of movable kidney, in 2 of horse-shoe kidney, in 2 of oxaluria and in 1 of Henoch's purpura hæmaturia was present; with accessory renal artery hæmaturia was occasionally present. In 9 cases hæmaturia was due to urethral calculus. There were 113 cases of cystitis in which hæmaturia was present, the hæmorrhage in all cases being moderate and often found only on microscopical examination. When visible it was usually of the terminal type. There were 72 cases of tumours of the bladder, in most of which the bleeding was severe and associated with the formation of massive clots in the bladder. In some cases, however, the hæmorrhage was trifling. In 34 cases of vesical calculus hæmaturia was present, the hæmorrhage varying from a microscopical to a moderate amount. The signs of stone in the bladder were sometimes obscure and the calculus was sometimes only accidentally discovered. The usual causes of ulceration of the bladder were tubercle and malignant disease. Superficial ulceration sometimes occurred in cystitis.

Bilharzia hæmatobia.—Two of these cases were included in the series. Hæmorrhage in cases of enlarged prostate was sometimes severe. Two cases of papillomata of the urethra were included.

The underlying cause suggested the right treatment.

Medical Aspect.

Professor J. A. **Lindsay** dealt with the subject from the medical point of view. Hæmaturia lay on the borderland of medicine and surgery, and while a large proportion of these cases rightly reverted to the surgeon, some belonged to the physician, who was often the first to see the patient. Omitting bladder, prostate, and urethral cases, hæmaturia might be divided into three groups.

In the first group diagnosis was more or less obvious. This group included hæmaturia from poisons—turpentine, cantharides, carbolic acid, &c.—cases connected with the infective fevers, cases depending upon general diseases, such as scurvy, purpura, hæmophilia, leukæmia; cases associated with heart disease. Where hæmaturia was a feature of heart disease inquiry should be made for ulcerative endocarditis. In the second group diagnosis, if not obvious, presented little difficulty. To this group belonged such conditions as granular kidney and oxaluria. A sharp hæmorrhage might be the first symptom to attract attention in granular kidney, but corroborative signs and symptoms would always be found upon examination. In the third group diagnosis often presented serious difficulty. To this group belonged tuberculosis of the kidney, calculus, and new growths. The examination of the urine was often indecisive, but the presence of renal casts, shreds of tumour, crystals, or micro-organisms might give the requisite clue. The cystoscope was of paramount importance, but Mr. Fullerton had given useful cautions as regards its indiscriminate use. Radiography was often of service, especially in the cases of calculus. Tuberculosis of the kidney was common, but was rarely primary. The diagnosis might present great difficulty. Early polyuria might occur, and later the presence of blood and pus and tubercle bacilli in the urine. Albuminuria might be present. The constitutional symptoms might be slight and the general health well maintained. The course of these cases was very variable, and remedies might get the credit which was really due to nature. There was much difference of opinion regarding the value of tuberculin. In certain cases operation was indicated. Calculus was not common in the North of Ireland. The usual type was oxalate of lime. Renal colic and hæmaturia were common, but might both be absent. Cystoscopy might show a unilateral diuresis and diminished specific gravity of the urine on one side. Radiography was of essential service. The early diagnosis of new growths in the kidney was of cardinal importance in view of the value of early operation. A sharp hæmorrhage with little pain, recurring at intervals, was often the earliest sign. The constitutional symptoms might be slight. A dull aching pain in one loin might appear early, but when a definite tumour was recognisable the case was already advanced. These cases should be explored, as their distinction from the cases known as "symptomless renal hæmaturia" might be difficult.

The treatment of hæmaturia depended upon cause. Only rarely was symptomatic treatment justifiable. There was no trustworthy astringent in renal hæmorrhage. Opium and calcium salts might be tried, but their value was doubtful.

In the subsequent discussion the following members took part: Dr. **John Campbell**, Dr. R. W. **Leslie**, Dr. W. **Calwell**, Dr. J. E. **MacIlwaine**, Mr. S. T. **Irwin**, and the **President**.—Mr. **Fullerton** replied.

LIVERPOOL MEDICAL INSTITUTION.

A **meeting** was held on Jan. 6th, with Dr. J. E. **Gemmell**, the President, in the chair, when Dr. C. J. **Macalister** read a short paper on

Left-handedness and Conditions Associated Therewith.

After referring to some of the theories concerning the hereditary explanations of right-handedness and left-handedness and the statistics concerning the proportionate incidence of the latter as compared with the former, he indicated that he did not wish it to be suggested that every case of left-handedness was liable to the functional disorders or ataxias to which he directs attention. By far the greatest number of left-handed people are perfectly normal physiologically, but he particularly referred to certain abnormalities which he felt sure depended upon transposed function. He showed a case of a left-handed girl, aged 13½, who was practically aphasic, whose language was one of signs and gesticulations resembling those natural ones used by the deaf. She had a fair amount of intelligence and a wonderful memory, her backwardness depending, to a certain extent, upon simple lack of education. She was being taught to sign and to read and write by the methods adopted among deaf-mutes.

He laid great stress upon ancestral and collateral history as bearing upon the question, and instanced cases of left-handed stammerers having left-handed relations and of right-handed stammerers also having a left-handed ancestral history. He suggested that in these cases of marked incoördinations occurring in the left-handed the right speech centre might be unbalanced by some unusual development of function of the left one, thus giving rise to a confusion of coördination. The same principle might apply to cases of chronic hemichorea. Having noted that although transposition of the viscera might be thought to be associated with left-handedness, this is not constantly the case, there being a good many records of this condition where there has been right-handedness.

He next emphasised the fact that a certain number of left-handed people have left speech centres, proved by those cases of cerebral hæmorrhage affecting the right speech motor area where there was no aphasia. He quoted cases described by Dr. Foster Kennedy in the *American Journal of Medical Sciences*, where injuries involving the right Brocal areas in left-handed people had not been associated with defects of speech, and another series of cases of right-handed people where involvements of the right Brocal areas had been associated with aphasia. The lesson derived from Dr. Kennedy's paper was that where there is a known hereditary or collateral history of left-handedness the speech centres appear to have been transposed, whereas in a number of cases of which no such history had been discovered transposition had not taken place. Dr. Macalister expressed his opinion that there might be a Mendelian explanation of this, and that the occasional incomplete cases as well as the complete ones might be the result of hybrid marriages.

Dr. **Dingwall Fordyce** read a paper on

Thyroid Function in Sick Children and its Influence on Treatment.

He stated that thyroid enlargement is a common phenomenon in the locality of Liverpool. He considered that there is reason for connecting gastrointestinal disorder with this cause and for expecting general lymphatic hyperplasia as a concomitant. This general condition is associated with symptoms markedly anaphylactic in nature. The clinical examples which he described varied markedly in intensity of symptoms and according to age.

ASSURANCE MEDICAL SOCIETY.

At a meeting of the society held on Nov. 3rd, 1920, the President, Dr. T. D. **Lister**, being in the chair, Dr. R. **Hingston Fox** opened a discussion on

Albuminuria in Relation to Life Assurance, especially in Adolescents,

by reading a paper which appears in full amongst our original articles this week.

The **President** said that Dr. Fox had thrown out a challenge to the physiologist and pathologist, to the physician and to the Assurance Medical Society, which he hoped they would take up.

Dr. **Ogier Ward** added a few facts of his own observation. In his last 1400 cases he found albumin present in 68, a percentage of 4·9. Of the 1010 cases over 30 albumin was present in 35, a percentage of 3·4. Of the 390 cases under 30 years of age albumin was present in 33, a percentage of 8·5. Of these 33 under 30 years of age 19 had nothing else against them, even in family history, beyond build, nerves, or bad teeth. He was now convinced that those 19 cases might one and all have been accepted at ordinary rates. That was tantamount to saying that where neither family history nor physical examination shows any of the other defects which called for extra rating the mere presence of albumin in an applicant well under 30 might be passed over as of no account.

Dr. HUGH MACLEAN said that the question of albuminuria had always been a difficult one. One came across numbers of cases undoubtedly in which there was no reason whatever to believe that the condition had any detrimental effect on the kidney, or, in other words, that the kidney was more liable to subsequent nephritis than was a normal kidney. It would be a great help if any tests could be carried out giving even a hint as to the causation of the condition. The relationship of the albumin to the globulin had been suggested as of value; also the presence of globulin, as indicated by the addition of 30 per cent. solution of acetic acid to the urine. Should a precipitate form, the presence was assumed of something which was called globulin, and it had been stated that this result with acetic acid was much more frequent in cases of physiological albuminuria than in albuminuria caused by nephritis. He had examined 60–70,000 cases of albuminuria in soldiers, testing all the urines of the first 10,000 that had a fair amount of protein with acetic acid; in only two or three cases was there any precipitate at all, and there were obviously many cases of undoubted functional albuminuria in which there was no acetic acid reaction. He also carried out the diastatic reaction in nearly all the albuminous urines from the first 10,000 cases, and the results were normal. To determine the relation of albumin and globulin was not within practical politics for an ordinary examination. There seemed to be some association between the presence of calcium oxalate crystals and albuminuria, and large numbers of such crystals might suggest that the condition was not pathological in the ordinary sense of the word. The significance of the cast was a difficult question. The presence of a few epithelial casts, he thought, justified the assumption of a definite kidney lesion which might or might not go on to nephritis. In a case in which it was difficult to say from the symptoms what the albuminuria amounted to, the urea concentration test might afford a good deal of help. It was exceedingly simple; the patient was given 15 g. of urea and asked to empty his bladder beforehand and again one hour afterwards, the amount of urea in the urine being estimated.

Dr. R. L. MACKENZIE WALLIS said that in examining a large number of schoolboys among whom there had been almost an epidemic of albuminuria, and also a number of medical students over a period of several years, the albuminuria had proved to be due mainly to euglobulin, the acetic acid test revealing its presence. He applied the test in the following order:—

> First test for the presence of protein; 3 to 6 drops of salicyl sulphonic acid are added to about 10 c.cm. of urine, and the appearance of a white precipitate noted. The presence of the particular type of globulin that occurs in adolescent albuminuria was determined by adding 3 to 6 drops of diluted acetic acid to 10 c.cm. of urine, when a white precipitate or opalescence appeared at once.

In a large number of cases a gelatinous precipitate appeared after a time, due to mucin and not euglobulin, and especially common in urine of high specific gravity and strongly acid reaction. To label cases as non-nephritic albuminuria required more thorough examination of the urine than was possible in insurance practice. The ratio of albumin to globulin in ordinary nephritis was generally 6 : 1, but in functional and adolescent albuminuria only 2 : 1. In leaky kidneys of the non-progressive type of albuminuria in older people the ratio was generally reversed. Many cases of adolescent albuminuria cleared up, but with intercurrent illness the albuminuria readily returned. A man,[1] aged 29, who had albuminuria with large quantities of euglobulin for 13 years, remaining in perfect health with no obvious signs of renal trouble, died of acute uræmia a month after the urine was examined. During that month albuminuric retinitis developed and all the signs of small white kidney. He was beginning to think that any form of albuminuria was pathologically dangerous. The whole question of why globulin appeared in the urine in certain conditions required further elucidation.

Sir DOUGLAS POWELL quoted a statement made with regard to the soldiers in France. Some albuminuria having been found in 5 per cent. of 50,000 men, yet of all the cases in which organic disease of the kidneys arose scarcely any came from the number of those in whom temporary albuminuria had been noted. His disposition would be to regard these functional cases of albuminuria as negligible and pass them as ordinary lives if perfectly sound in every other respect.

The PRESIDENT emphasised the difficulty in diagnosing the adolescent type from other types of albuminuria in adolescents. He asked Dr. Wallis and Dr. Maclean whether they had observed under the microscope the centrifuged deposit in their cases of albuminuria, and whether they made blood pressure examinations.

Dr. MACLEAN said that out of the total of cases he had examined 5–6 per cent. had albuminuria, 2 per cent. in marked degree albuminuria, and something over 1 per cent. had fair numbers of casts. There was no opportunity of doing blood pressure experiments in France, but at home he had not found that the administration of urea exerted any effect on the pressure. Among certain cases of non-nephritic type of albuminuria the blood pressure was distinctly low and oxalates were found in the centrifuged deposits.

Dr. MACKENZIE WALLIS said he had noticed the constancy of oxalates in these cases of adolescent albuminuria. In a centrifugalised deposit he did not pay much attention to the presence of hyaline casts. With regard to blood pressure, that had been recorded in nearly all his cases, and was generally normal. The patient whom he had described had a normal blood pressure for 13 years; then he had an illness and developed albuminuria, and up went the blood pressure at once to over 200 mm. Hg.

Dr. LANGDON BROWN thought that a patient under 30 without other signs might be regarded as a normal risk. The globulin test was important, and had the advantage of being easily applied. Some people passed mucin and not albumin or globulin at all. He agreed with regard to the liability of a person who had had functional albuminuria to a return under strain of illness. The experience of school medical officers was of value. Dr. Clement Dukes had taken every opportunity he could to test old Rugbeians who had had "functional" albuminuria, and only in one of those cases had albuminuria persisted in later life. Functional albuminuria below 30 years of age was very important from the life assurance point of view, because of the number of cases; leaky kidneys were so rare as to be unimportant.

The Discussion Resumed.

When the discussion was resumed on Jan. 5th Dr. F. PARKES WEBER divided the albuminuria of youth and early adult life from the point of view of prognosis and examinations for life assurance and appointments into four main classes:—

1. Albuminuria connected with definite nephritis, chronic heart disease, acute febrile diseases, amyloid disease, and other conditions, such as are met with in hospital wards and ordinary medical practice. In these cases the amount of extra on the life should depend on a variety of circumstances—for instance, the presence or absence of tube-casts, the amount of the leakage of albumin, the results of various tests as to efficient functional activity of the kidneys, the length of time that the albuminuria had lasted, the blood pressure, and the condition of the candidate in other respects.

2. Transient albuminuria due to various causes. In

---

[1] This case was recorded by Dr. Ivor J. Davies in THE LANCET of Dec. 18th, 1920, p. 1249.

such cases several examinations were often required before the life could be regarded as a first-class one.

3. Postural or orthostatic albuminuria. In uncomplicated cases of orthostatic albuminuria he was convinced that the life might be regarded as a normal one from the life assurance point of view. No young person should be prevented from living an ordinary active life merely because of the presence of orthostatic albuminuria. In regard to prognosis help might be obtained by estimating the relative proportions of serum-albumin and globulin in the urine, but it was of at least as great importance to ascertain whether albumin was altogether absent from the urine passed immediately on getting out of bed in the morning.

4. The presence of albumin (frequently only a trace) accompanying minute quantities of pus, blood, or semen in the urine. The slight opacity in the urine in these cases might easily be overlooked, or wrongly neglected *as of no importance, in examinations for life assurance.*

Sir **JAMES GALLOWAY**, Dr. **H. BATTY SHAW**, Dr. **H. M. ABEL**, Dr. **H. W. COLLIER**, Dr. **F. G. CHANDLER**, and Dr. **A. WITHERS GREEN** also spoke.

Dr. **HINGSTON FOX**, in replying, suggested that the interesting case of a rare form of albuminuria described by Dr. Wallis and others did not fall into the category under discussion, for there was continuous high arterial tension, albumin was present in large quantity, and persisted during bodily rest. Evidently the tests for the efficiency of kidney function were not yet in a position to be fully relied on; he hoped more work would be done with the urea-concentration test in albuminuric cases. The discussion had led to a fuller recognition of a type of albuminuria, occurring commonly in adolescence, harmless in its nature and independent of any disease of the kidney. Dr. Fox concluded by citing a table (prepared for him by the kind offices of Mr. F. J. Cameron, of the Friends' Provident and Century Life Office) showing the mortality of assurers in whose urine albumin was found once, at entrance or within two years previously, but no casts were reported present. The lives were very carefully selected and few, if any, taken "until there was reason to believe that the presence of albumin was temporary and unimportant." The policies were issued in the 24 years 1885 to 1908, and the period of observation varied much; in about two-thirds of the whole number of lives it was five years or less.[2]

Ages at entry.	Actual deaths.	Expected deaths.	Ratio of mortality.
15-29	70	65·16	107%
30-39	58	43·75	133%
40-49	37	33·47	110%
50-59	29	27·20	107%
60-end	8	5·48	146%
All ages	202	175·06	115%

It would be seen that for those entering in adolescence, before the age of 30 years, the mortality hardly exceeded the normal for healthy lives, while there was a considerable rise for those entering in the next decade.

SOCIETY FOR THE STUDY OF INEBRIETY.

AT a meeting of this society, held in the rooms of the Medical Society of London on Jan. 11th, Sir **ALFRED PEARCE GOULD** presiding. Dr. **H. M. VERNON** opened a discussion on

Alcohol and Industrial Efficiency.

At the present time, he said, public opinion would not sanction any direct limitation in the amount of alcohol consumed, but temperance could be promoted by the physiological regulation of the conditions of drinking. It was easier to investigate the effects of alcohol on the efficiency of manual workers than on that of the non-manual, but the conclusions arrived at concerning the importance of regulation in the former class apply equally to all workers. The effects of alcohol on typewriting were systematically studied, as this was a class of manual work in which accuracy and speed could be easily measured. The subjects of experiment typed a memorised passage at frequent intervals before and after drinking the alcoholic liquid, and it was found that in each of the seven subjects the adverse effect of the alcohol was about twice as great when it was taken 3¼ hours after food, or on an empty stomach, as when it was taken with food. In a fresh series of experiments Dr. Vernon drank whisky containing 45 c.cm. (1½ oz.) of alcohol at various periods after a substantial meal had been eaten. He found that whilst the effect produced was comparatively slight up to two hours after food, it then underwent a sudden jump, and 3½ hours after food the effect was increased to more than double. With more prolonged fasting (up to 20 hours) the effect became greater still. When vigorous exercise was taken at the end of a 13 hours' fast the effect of the alcohol was greatest of all, and for a few minutes induced a condition not far removed from intoxication. Conditions similar to the experimental ones described were sometimes observed in industrial workers before the war, when they worked hard for two or three hours in the early morning on an empty stomach and in the breakfast interval visited the public-houses (then open at 5 to 8 A.M.) before eating food. On comparing the toxicity of beers containing 5, 4, and 3 per cent. of alcohol (by volume) it was found that dilution had a much more than proportionate effect in reducing toxicity. For instance, 90 c.cm. of alcohol taken in the form of 3 per cent. beer produced only as much effect as 46 c.cm. of alcohol in the form of 5 per cent. beer. In fact, the speaker concluded that it was practically impossible to get intoxicated on beer containing 3 per cent. of alcohol. This conclusion was borne out by what is observed in Denmark, where the Government allow beer containing 2·6 per cent. (by volume) of alcohol to be produced and sold free of all taxation, though the stronger beers are taxed, and are therefore more expensive. In consequence of this policy intoxication has almost ceased, and it is suggested that in this country a scheme of graduated taxation of beers of different gravity—such as was brought forward (without success) by the Chancellor of the Exchequer in 1915—would greatly increase sobriety. In confirmation of previous results he found that the toxic effects of whisky reached their maximum at 10 per cent. alcoholic strength (by volume), and at this concentration they were just as great as that of neat whisky 15° to 50° under proof. Hence, spirit-drinkers, by diluting their spirits moderately, would reduce the injurious action on the gastric mucous membrane without diminishing the alcohol sensation they desire. The typewriting method showed that alcohol disappeared from the human body at about the same slow rate as Mellanby found it to disappear in the dog. In Dr. Vernon's own case it was got rid of at the rate of about 13 c.cm. per hour, or nearly half an ounce. In that a pint of fairly heavy beer contained an ounce of alcohol, it followed that if a man drank a pint every two hours (as was observed during the daytime in some industrial drinkers before the war) his blood was never free from alcohol. The policy of the Central Control Board in shutting the public-houses for part of the day was valuable in checking this continuous drinking.

Discussion.

An interesting discussion followed. Dr. **M. GREENWOOD** spoke of the danger of the return to pre-war inebriety, when drink made industrial conditions less intolerable for the working classes. We must aim at a more ideal life for the worker, at the same time continuing the limitation in the hours during which public-houses were open. Miss **SQUIRE** lamented the failure to produce a popular drink which could be consumed with impunity. Good food had made an enormous difference to the physical and moral wellbeing of the munition workers during the war. The canteen had been a distinct achievement in the path of progress. Mr. **NICHOLSON** said that prohibition, whatever its merits, was looked upon as a class measure by the labouring man, and Mr. **THEODORE NEILD** added that in America an attempt was being made to eliminate the saloon without stopping the sale of liquor. The importance of a low-gravity beer was brought out in other contributions to the discussion.

---

[2] Of the 202 cases, in 152 no examination was made for casts. On account of the smallness of the numbers the two groups had been combined. The effect of medical selection during the earlier years after entry had been duly allowed for in the "expected deaths."

leader of extraordinary intelligence—e.g., Mr. Seaton Thompson's *Lobo*. If we allow Mr. Read's Lycopitheeus to have arrived at the stage of developing imagination, we may equally allow the leader of the pack to have been endowed with extra intelligence and to have assumed or to have been credited with powers, belief in which may have been due to "illusory imaginations" in the subordinate members of the pack, but about which he himself had no illusions. That is to say, that the first priest or the first wizard may only have been a primitive man gifted with more intellect than his fellows and with "imagination" in the right sense of the word—i.e., the sense in which Tyndall wrote of the scientific use of the imagination, to which Mr. Read refers on p. 74. We see that on p. 337 Mr. Read allows that rain-makers learn to "operate for rain only when rain may reasonably be expected," and we do not see why the primitive wise man should apparently be credited with deception. It is interesting to note that an instance of rain or rather thunder making occurs among so civilised a people as the French so late as the seventeenth century, certainly a good example of illusory imagination. In Pepys's Diary for August 21st, 1665–6, there is the following delightful story:—

> "Mr. Batelier told me how, being with some others at Bourdeaux, making a bargain with another man at a taverne for some clarets, they did hire a fellow to thunder (which he had the art of doing upon a deale board), and to rain and hail, that is make the noise of, so as to give them a pretence of undervaluing their merchants' wines, by saying this thunder would spoil and turn them. Which was so reasonable to the merchant, that he did abate two pistolls per ton for the wine in belief of that."

If the Bourdeaux fellow with the board had lived in primitive times he would have been a most valuable acquisition to his pack, and we hope that he escaped the fate of the other well-known thunder-maker, Salmoneus, who came to a bad end as recorded in the Æneid.

The second and by far the larger portion of Mr. Read's book deals with magic, animism, and totemism. He ends on a sad note. Animistic illusions have in the past been the influence owing to which

> "nations have hitherto submitted to and enforced law and order ..... it is now everywhere noticeable in the more civilised countries that these illusions are being dissipated, and it is very difficult to judge how people will behave when they are gone. ...... Whilst some beliefs concerning supernatural things are being lost, others are being resuscitated: but the lapsing beliefs are noble and venerable, and have exerted great public power and authority; whilst those now eagerly propagated are the raw infatuation of quacks, on a level with the animism of an Australian medicine-man—and indeed much inferior to his, as having no moral influence or authority. What must come of this is so dubious as to discourage one about the future of the world." (Pp. 342–343.)

We fear that Mr. Read's doubts have only too much justification. Emerson was right when he said, "When half gods go, the gods arrive," but nowadays it looks as though the converse were true, and that we should say, "When the gods go half gods arrive." Still, it must be allowed that the world is as a whole better than it used to be, and it is a fact of history that when the world has seemed at its worst a Saviour, divine or human, has come to the rescue, from the time of the first Christmas down through the ages by the voice and example of Francis, Dominic, Ignatius, Wesley, and the countless thousands who have spent themselves to make men better.

Midwifery for Nurses.

A Practical Text-book. Seventh edition, revised and enlarged. By ROBERT JARDINE, M.D. Edin., F.R.S., Professor of Midwifery, St. Mungo's College, Glasgow. London: Henry Kimpton. 1920. With 60 illustrations and 3 plates. Pp. 296. 7*s.* 6*d.*

VERY little commendation is required for a book which has reached its seventh edition. This in itself is evidence of its usefulness and popularity. The book has undergone an extensive revision and has been enlarged. It is a good and sound guide for the midwifery nurse, and bears the imprint of the author's large clinical experience. We notice with regret that an old inaccurate figure from Playfair is reproduced, and in a book of this kind plates representing fœtal monsters seem a little out of place.

Operative Gynæcology.

Second edition. By HARRY STURGEON CROSSEN, M.D., F.A.C.S. London: Henry Kimpton. 1920. With 834 illustrations. Pp. 717. 63*s.* net.

THIS very interesting and instructive book includes a systematic presentation of almost all the operative procedures available for the treatment of any gynæcological condition. As the author rightly states in his preface, the best results both for the patient and the operator are likely to be obtained when the surgeon carefully selects that operation which is the most suitable in any given case. The aim of this work is to render such a selection on the part of the operator easier and more certain. For this reason a very wide range of operations is included, and we find no less than 109 pages devoted to a consideration of the different methods of dealing with retro-displacements and some 75 pages to the operations for prolapse and inversion of the uterus. The operative procedures are clearly described and well illustrated. There is a very full account of the various operations for dealing with fibroid tumour of the uterus. We notice with surprise, however, the recommendation to clamp the pedicle of a fibroid polypus, an entirely unnecessary procedure. Not only is the operation of extended abdominal hysterectomy well described, but there is also a very good account of the method of treating cancer of the uterus by heat as carried out by Percy. We are surprised to see so little allusion to the treatment of this condition by radium, nor can we find any mention of radium in the index. The author is in favour of removing ovarian cysts without preliminary tapping, and in this no doubt he is right.

A very interesting section is devoted to foreign bodies left in the abdomen, and the medico-legal aspect of such cases is considered. The author has done a good service in substituting a nomenclature of definite anatomical terms for many operations hitherto known mainly by the name of their originator. In this second edition much new matter has been added and some 60 new illustrations. The book reflects much credit on its author, and will be of great assistance to the gynæcological surgeon.

Obstetrics, Normal and Operative.

Third edition. By GEORGE PEASLEE SHEARS, B.S., M.D., Professor of Obstetrics and Attending Obstetrician at the New York Polyclinic Medical School and Hospital. Revised by P. F. WILLIAMS, Ph.B., M.D., Instructor in Obstetrics, School of Medicine, University of Pennsylvania. London and Philadelphia: J. B. Lippincott Company. With 423 illustrations. 1920. Pp. 745. 35*s.*

IN the third edition of this book a considerable amount of revision has been carried out, although in essential details it remains unaltered. The volume contains a good account of the important facts of obstetrics and is interesting as an example of the teaching in an important American school. In the diagnosis of pregnancy considerable importance is laid on abdominal palpation, and not only the recognition of the anterior shoulder but its exact location in regard to the middle line and the symphysis pubis is shown to be of much value. The section on anæsthesia in labour has been added to and there is a good account of the method of employing nitrous oxide oxygen analgesia in labour. The authors are not on the whole in favour of twilight sleep and do not practise this method to any extent. The section on backward displacements of the uterus complicating pregnancy is disappointing and the authors are too ready to recommend unnecessary and early interference. In the chapter dealing with extra-uterine pregnancy nothing is said of Taylor's work on advanced extra-uterine gestation and of the important distinctions demonstrated by him in the anatomical relations of these cases. The authors are wrong in imagining that the great advantage of placing the patient upon her side in difficult cases of bringing down a leg in impacted breech presentations is not generally recognised by obstetricians; the procedure is, as a matter of fact, commonly taught in this country. Considerable additions have been made to the sections dealing with Cæsarean section and the toxæmias of pregnancy. The book is a good one of its kind and clearly written.

THE SCHOOL OF SALERNUM

And the Regimen Sanitatis Salernitanum, with the English version of Sir John Harington, 1607. Together with a History of the School of Salernum. By FRANCIS PACKARD, M.D., and a note on the Prehistory of the Regimen Sanitatis. By FIELDING H. GARRISON, M.D. New York: Paul B. Hoeber. 1920. Pp. 214. $3.75.

THE School of Salerno and the Regimen Sanitatis are subjects of perennial interest, not merely from their intrinsic qualities but also because the origin of both is a matter of hopeless obscurity. In this edition of the Regimen, which includes a Latin text as well as Harington's translation, Dr. Packard and Dr. Garrison have written essays which gather up all that is known about the origin of both the School and the Regimen, and it does not amount to much. What evidence there is, is chiefly of a negative order—for example, there is not a particle of historical foundation for the theory that the rise of the School can be connected with the Benedictine House of Monte Casino.

The School of Salerno is now but a name, but the Regimen remains as a typical example of a mediæval popular treatise on medicine and the care of the health, one, moreover, which contains much sound sense; Harington's translation is well worth reading though not very literal. The book is well printed and the text is illuminated here and there by illustrations, some of them reproductions of German woodcuts of the sixteenth century, in all of which the execution is coarse, and in some of them the subjects as well.

PHYSICAL CHEMISTRY IN MEDICINE.

Die Physikalische Chemie in der Inneren Medizin: Die Anwendung und die Bedeutung der physicochemischen Forschung in der Pathologie und Therapie. Für Studierende und Aerzte. Von Prof. Dr. H. SCHADE, Vorsteher der physicochemischen Abteilung der medizinischen Universitäts-Klinik in Kiel. Dresden und Leipzig: Verlag von Theodor Steinkopff. 1921. Pp. vii. + 569. £1 1*s.*

PHYSICAL chemistry is now established as a distinct and definite part of physiology, medicine, and pathology, but it is scarcely realised that its ramifications extend over almost the whole range of medicine. The appearance of Professor Schade's book is therefore very welcome, for it summarises and explains various medical and pathological phenomena by physicochemical reactions. In the past we have relied largely upon histological evidence for an explanation. This evidence is not a real explanation; it merely indicates that something abnormal has occurred and a theoretical discussion on a biological basis has followed. No single physico-chemical process gives us sufficient information, but by a coördination of several processes we advance nearer to a better conception of certain pathological conditions.

As an illustration of the complexity of the processes occurring in disease, we may merely instance the author's interpretation of the phenomena of inflammation. The injury, caused by an external agent, first produces a change in the colloidal state of the cell protoplasm, such as an alteration of surface tension. The purely mechanical method of flow of light and heavy particles in a moving liquid, the lighter particles being at the edges, accounts for the movement of the leucocytes along the walls of the blood-vessels, so that they come into contact with the damaged tissue. The alteration in surface tension of the damaged cells causes the arrest of the leucocytes. The wandering of the leucocytes into the injured tissue probably corresponds to the streaming of droplets in a fluid in a direction opposite to the flow of substances lowering surface tension. At the same time the permeability of the cell wall is changed; its porosity is increased so that albumins and globulins can pass through to form the exudate. All three processes effect a conversion of the particular colloidal state to the *sol* form. Substances, such as the autolytic enzymes, are produced which hydrolyse the complex molecules of albumins, fats, &c., to smaller ones. The cell contents thus become hypertonic and liquid flows into the damaged area causing swelling. A calculation indicates that the osmotic pressure may reach 8 to 11 atmospheres. The high pressure affects the blood circulation to this area producing a diminished flow; the lymph circulation is also affected. It is the osmotic pressure change which causes the pain, and the actual pressure sets up the throbbing. The local heat appears to be the result of the intensive chemical changes set up, the heat not being carried away fast enough by the diminished blood flow. The various processes occurring may be summed up as being purely chemical, purely physical, and physico-chemical—namely, osmotic, ionic, colloidal, fermentative.

Throughout the book the author gives an equally clear description of other pathological conditions and we can recommend his book as an outline of this vast and important subject. The reader is helped to understand the complexities by a short account, in the first section of the book, of those parts of physical chemistry of importance in medicine, the last section being devoted to the practical description of these methods which would require some amplification for a novice, but which are most excellent for any worker with experience of physical chemistry.

PYORRHŒA ALVEOLARIS IN ITS CLINICAL ASPECT.

By D. A. CROW, M.B., Ch.B. Edin., Assistant Surgeon to the Sussex Throat and Ear Hospital, Brighton. With Foreword by Sir FRANK COLYER, F.R.C.S., L.D.S. Eng., Dental Surgeon, Charing Cross Hospital, and Royal Dental Hospital, London. London: Baillière, Tindall, and Cox. 1921. Pp. 111. 6*s.*

THE object of this little book, as stated in its introduction, is "to emphasise once again the overwhelming importance of pyorrhœa alveolaris in the causation of many of the diseases and minor complaints met with in medical practice." The chapters deal with clinical signs, X ray appearances, symptoms local and general, the neglect of pyorrhœa in classical medical literature, its treatment and prognosis. There follow a summary and analysis of 100 cases and an explanatory pamphlet for patients, which is by far the weakest section of an otherwise well-planned and pleasantly written treatise. Unfortunately the ætiology of the disease is still too obscure and debatable for any attempt to educate the public in prevention to be convincing. They are told that mouth-breathing should be avoided, and that (p. 110) "it is possible, but not certain, that a modification of diet would have a preventive influence in pyorrhœa." In an admirable foreword Sir Frank Colyer points out that the disease is neither of recent origin nor restricted in locality, and gives certain definite rules for maintaining the hygiene of the mouth in the young. Sir Frank Colyer agrees with Dr. Crow that the disease having once become established, neither physic nor vaccine-therapy is of use, and that extraction of every diseased tooth is the sole means by which a patient can be freed from the source of sepsis.

COMPENDIUM DER AUGENHEILKUNDE.

Für Studierende und Aertze. Eleventh and twelfth revised editions. By Professor Dr. PAUL SILEX. Berlin: S. Karger. 1920. With 95 figures and 2 coloured plates. Pp. 301. M.20.

THIS appears to be by no means a mere boil down of larger works, but a reliable introduction to the subject written by a man who has had considerable experience of teaching. The book, moreover, is small enough to be conveniently carried in the pocket. As a commendable example of simplicity we may cite the advice to use clean water as an eyewash in hyperæmia of the conjunctiva, and to permit smoking out of doors provided the pipe is sufficiently long. The ordinary rules for diagnosis and treatment are clearly expressed. The part devoted to operative surgery is somewhat meagre, the description of the operation for cataract, for example, being without any figure that would make it intelligible to the novice. The operative treatment of glaucoma, too, is barely indicated. On the other hand, two pages are devoted to a subject which one does not expect to find discussed in an elementary treatise of this kind—namely, the therapeutic employment of light and ultra-violet rays. A mercury vapour lamp (or an arc light) is used from which all the rays are screened off, save only those which it is desired to employ for the therapeutical purpose. Ultra-violet rays of wave length 300 μμ to 360 μμ are all absorbed by the cornea, and, if injudiciously applied, may cause an alarming reaction. Periodical exposures lasting from 5 to 20 minutes, however, are recommended as a treatment for corneal opacities.

We notice, what is not very usual in German text-books, the recognition of some English authorities, though in the pages devoted to colour blindness (which are so far up to date that the Holmgren wool test is stated to be fallacious) no reference is made to the work of Edridge-Green. In the section on Workmen's Compensation formulæ and tables are given to aid in the assessment of the loss of earning power due to injuries resulting in loss of vision of various degrees, in either one or both eyes. The Germans have a longer experience of workmen's compensation laws than we have, and those interested in this subject will find it useful to consult these tables.

ANNALS OF MEDICAL HISTORY, 1919. Vol. II., No. 4. New York: Paul B. Hoeber. Pp. 407. $2.50.

"Annals of Medical History" is always an interesting publication, and the number before us is particularly so. The first article by Dr. F. H. Garrison and Dr. E. C. Streeter deals with Sculpture and Painting as Modes of Anatomical Illustration, and traces the progress of anatomy in art from the earliest days of the Aurignacian period down to modern times. The authors' thesis is "that genuine anatomic illustration arose not in didactic hand drawings made by physicians, but without didactic intention, in the sculptures and figure paintings of the great Florentines." Dr. John E. Lane writes about Daniel Turner (1667–1741), the recipient of the first degree of Doctor of Medicine conferred in the English colonies of North America by Yale College in 1723. Turner, though a Licentiate of the Royal College of Physicians, was anxious for a medical degree, and apparently did not hold the Scottish degrees in high estimation. So he wrote a Latin letter to the authorities of Yale University offering them a gift of books, appended to which was a postscript in the regular schoolboy style of "PS.—Please send me a cake," and it ran thus:—

> "Si Dominationes vestrae me dignum judicatis Doctoratus Gradus Academiae Yalensis, et diploma mihi transmitti curatis, accipiam non tantum ut signum Gratitudinis Vestrae," &c.

Turner is chiefly remembered to-day by Turner's cerate, a calamine ointment.

Dr. John Ruhrah contributes an article upon Thomas Phayer or Phaer (1510?–1560), author of the first English book on the diseases of children. Dr. Ruhrah has collected a vast amount of information about Phayer, but unfortunately his article is marred by several careless statements and some gross misprints. To give an instance: Phayer composed a treatise on the plague, some extracts from which, says Dr. Ruhrah, were "used by Henry Holland in an appendix to 'Spiritual Preservatives against the Pestilence.' ...... This Henry Holland was a son of a physician, Philemon Holland, and was as assiduous a translator as ever existed, who also did the 'Regimen Sanitatis Salerni' into English." This is a muddled statement. Philemon Holland was the assiduous translator, not his son Henry, and though Henry, the son of Philemon, did translate the Regimen, the Henry Holland who wrote "Spiritual Preservatives" was another Henry Holland, a divine who wrote the book in 1593, when Henry, son of Philemon, was only 10 years old. In quoting Chaloner's epitaph on Phayer, in which reference is made to an accident sustained by the latter, Chaloner's lines—

> "Nam domini culter, quis vitet fata? cruorem
> Hauserat ......"

are printed—

> "Nam domini culter, quis vitet fata? Cruorum
> Housorat ......"

which makes nonsense. Outside of his professional writings Phayer won great praise by his translation into English of the Æneid, or rather of the first nine books and part of the tenth, the remainder being translated by Thomas Twine. It is curious that the last lines he translated on the day before his death were (Bk. X., 467–469):—

> "Stat sua cuique dies, breve et inreparabile tempus
> Omnibus est vitae; sed famam extendere factis,
> Hoc virtutis opus."

LES ANTIGÈNES ET LES ANTICORPS. By M. NICOLLE. Paris: Masson et Cie. 1920. Pp. 115. Fr.4.50.

THIS small monograph comprises the Harben lectures for 1920, delivered by Professor Nicolle before the Royal Institute of Public Health in London. The lectures, three in all, have also been published, more or less contemporaneously, in English, in the *Journal of State Medicine* for October, November, and December. The first lecture deals with the general characters of antigens and antibodies. The author classifies all toxins into three categories: (1) neurotoxins; (2) toxins generating dry slough; and (3) toxins generating damp slough. He points out that these toxins contain two distinct elements, active and inactive, or have, in other words, non-antigenic and antigenic properties. Interaction between antibody and antigen takes place by means of two processes, coagulation and lysis, the former active in the absence of complement.

The second lecture deals with the diagnostic applications of antigens. Here the author discusses the relative value of precipitation, agglutination, and complement-fixation as a means of classifying bacteria, and his remarks on the numerous pitfalls in the application of these methods will be endorsed by every bacteriologist. Indeed, the author's short homily on technique will appeal to all laboratory workers:—

> "Employer toujours les mêmes antigènes ......choisir les échantillons qui offrent les reactions les plus spécifiques; les garder dans les meilleures conditions; s'assurer fréquemment que leur sensibilité aux anticorps homologues n'a varié ni quantitativement, ni qualitativement ...... Travailler toujours dans les conditions identiques. Faire toujours des témoins. ......"

In the third paper Professor Nicolle discusses the therapeutic application of these principles, based chiefly on his own extensive experience in preparing anti-sera during the war. In this connexion he is careful to distinguish between: (1) pathogenicity or the ability to produce morbid lesions; (2) toxicity or production of a specific poison; and (3) virulence or ability to multiply in the tissues.

JOURNALS.

Brain. Vol. XLIII. Part 3. 1920.—The Symptom-Complexes of Lethargic Encephalitis, with Special Reference to Involuntary Muscular Contractions, by F. R. Walshe. The author pleads for the classification of the symptoms of any toxic infective disease of the nervous system according to an anatomical plan. By this means much confusion would be obviated. He instances encephalitis lethargica as a case in point, and shows how such a term as "myoclonus" may be used with varying significance by different authors. Application of a natural classification of symptoms in lethargic encephalitis has led him to the conclusion that whereas in the production of negative or paralytic symptoms the virus has shown a selective action on the cells of the basal ganglia and brain-stem, in its irritant effect it appears to act equally on any and every part of the nervous system.—On Decerebrate Rigidity in Man and the Occurrence of Tonic Fits, by S. A. Kinnier Wilson. This paper is considered elsewhere in THE LANCET.—Relation of the Form of the Knee jerk and Patellar Clonus to Muscle Tonus, by H. Viets. Experiments on cats, both spinal and decerebrate, showed that in the former the knee-jerk is a single twitch, in the latter a single twitch followed by a continued contraction of the muscle. This is the "plastic element" in the phenomenon, and it is an indication of muscle tonus. A certain degree of tonus is necessary for the production of clonus; this is termed the "neutral tension" of the muscle, and is a neutral point between the reflex tonus and the weight of the limb; if the tonus be raised or lowered from this "neutral tension" clonus will cease. This study of the form of the knee-jerk was necessarily performed on animals, because in man there are so many factors which cannot be controlled, such as voluntary inhibition of the reflex.—Alterations of the Golgi Apparatus in Nerve Cells, by W. G. Penfield. Variations in nerve-cell activity induced by tetanus, strychnine in doses sufficient to cause repeated convulsions, decerebation and high section of the cord produced no change in the appearance of the Golgi apparatus. The apparatus exhibited a delicate and specific response to a lesion of its axone outgrowth, whether central or peripheral. This feature, retispersion, is ordinarily the first, and in some cases the only manifestation of chromatolysis. By retispersion the author indicates the dispersion of the Golgi apparatus to the periphery of the cell.

American Journal of Ophthalmology. July to December, 1920.—July: S. L. Olsho, The Coördination of Refraction with Spectacle and Eyeglass Fitting. This is a useful article, containing several points about the fitting of frames which are not to be found in ordinary text-books. The author has devised a new trial frame adjustable for faces which are unsymmetrical as to the level of the two eyes. —M. Fringold, Peripheral Communicating Vessels between Retina and Choroid; Fold of Inner Limiting Membrane in Chorioretinitis. An anastomosis between the retinal and choroidal venous circulation is an ophthalmoscopic curiosity. A case was shown at a meeting of the Ophthalmological Society of the United Kingdon by A. Lawson in 1910. This paper gives drawings of three similar cases, one of them with an added anomaly attributed to a fold of the membrana limitans interna. Another similar case of peripheral communicating vessels, probably congenital, is described and figured in the November number of the same journal, by H. S. Gradle.—The July number also contains papers on Wasp-sting Keratitis with Special Colour Changes in the Iris, by Y. Yoshida; on Apparent Sympathetic Ophthalmia nine months after Enucleation, with Implantation of Gold Ball in Tenon's Capsule, by D. N. Dennis; on a case of Ocular Pemphigus, by W. Campbell Pisey; and a note by H. V. Würdemann on a case of Embolism of the Central Artery of the Retina where the circulation was restored by forcible massage applied within a few hours of the onset of blindness. The number of similar cases previously published is 15.

August: The original papers in this number include one by V. Morax on Cataract Operations on Glaucomatous Patients; one by Y. Matsuoka on the Nature of the So-called Blood Infiltration of the Cornea; and one by W. L. Benedict on the Early Diagnosis of Pituitary Tumour with Ocular Phenomena—this last is illustrated by a coloured plate showing different stages in the development of optic atrophy in this disease.—H. J. Howard discusses the Origin of the Vitreous and a note by Aaron Brav suggesting the term "retinitis disciformis" in place of the descriptive but unscientific phrase "hole in the macula," by which cases presenting this appearance have usually been described.

September: F. M. Fernandez, Multiple Aneurysms of the Retinal Arteries. A coloured plate illustrates a very rare condition, which in this case was accompanied by profuse retinal hæmorrhages. The patient died from cerebral hæmorrhage 40 days after the first consultation. The prognosis in these cases appears to depend principally upon the presence or absence of retinal hæmorrhages. A case was described by J. A. Pringle in 1917 without hæmorrhages which he took to be congenital.—W. S. Franklin and F. C. Cordes, Radium for Cataract. This subject is being studied in the Department of Ophthalmology in the University of California. A method of application is employed by which all but the "gamma" rays are screened off. Details of the treatment applied to 31 patients affected with incipient cataract are given in tabular form. The conclusions arrived at are as follows: (1) the application of radium does no injury to the normal structures of the eye; (2) it apparently has a selective action on the lens; (3) radium improved the vision in 84·3 per cent. of the cases for which it was used; (4) a consistent technique and known dosage seem advisable; (5) frequent treatments are necessary in the beginning.—F. T. Tooke, Three Unusual Cases of Foreign Bodies in and about the Eyeball. The first of these cases was that of a Canadian soldier, who had been blinded by the explosion of a hand grenade. One eye had been entirely destroyed and enucleated, and from the other a large piece of steel was removed. The eye was so disorganised by traumatic cataract and irido-cyclitis that at one time its enucleation was considered on account of the pain. For six months he was at St. Dunstan's, and two years after the accident was returned to Canada. There a successful needling was performed resulting in vision 6/12 and with J.2 with a + 10 lens. In the second case, also a war case, a small foreign body, after being lodged in the interior of the globe for a long period, was extracted with the help of the Haab magnet by the anterior route, and a visual acuity of 6/12 was obtained. In the third case the patient kept a piece of steel in his eyeball for 14 years. About once a year it caused an attack of slight pain and inflammation. Ultimately the foreign body found its way into the anterior chamber, apparently as the result of the patient's habit of sleeping on his chest with his face buried in the pillow. The foreign body was extracted, leaving the eye blind from detached retina.—W. Zentmayer, Recurrent Retinal Hæmorrhages. A. E. Davis, Recurrent Retinal Hæmorrhage of Adolescence. These two papers give case-histories of this disease, which was first described by the late Mr. Eales, of Birmingham, about 40 years ago. Its pathology is still obscure, but it may probably be a tuberculous affection of the retinal vessels. The first of these papers suggests that an interference with the functions of the ductless glands—probably the adrenals—may also be a factor in its causation.—The number also contains articles by E. Scott and F. F. Schmidt on Intradural Tumours of the Optic Nerve, with report of a case.—Also three articles by E. J. Brown, Homer E. Smith, and M. Goldenberg on Different Aspects of the Glaucoma Problem.

October: Gordon M. Byers, Reticular Keratitis. Partially opaque lines in the corneal substance may be due to a wrinkling of Descemet's membrane, such as occurs after some cases of cataract extraction ("keratitis striata"), or they may be found in eyes with persistently low tension, when they are due to wrinkling of Bowman's membrane—a series of cases of this sort was described by Holmes Spicer in 1916, under the name of superficial linear keratitis. Other cases, again, have been figured where the opacities, instead of forming approximately parallel lines, constitute a network. The case figured in this paper belongs to this last variety, but the author suggests that it belongs to the same group as Spicer's cases, and that the term "reticular keratitis" ought to be replaced by some such phrase as "anterior corneal corrugations."—Ignacio Barraquer, Phakoerisis. This word is used to designate a cataract operation performed at Barcelona on some thousand cases. The method is one of suction performed with a specially constructed aspirator through an ordinary corneal incision.—Other papers dealing with cataract are by G. R. O'Connor, who criticises adversely Smith's intracapsular operation, by H. W. Woodruff on Safety Procedures, and by W. A. Fisher on Delirium Following Cataract Operations.—W. R. Parker contributes a paper on a case of Cerebral Tumour involving the Right Optic Tract, Chiasm, and Adjacent Brain Substance, with charts showing the progressive loss of visual field.—The last original paper is by M. Lombardo, reviewing the literature of post-diphtheritic ocular paralysis.

November: H. Gifford, Rupture of Cornea by Contrecoup from Bullet Wound of Orbit. The paper proves the possibility of this occurrence, the observations on humans being confirmed by experiments on anæsthetised dogs.—V. B. Blair, Report of Two Cases of Kroenlein's Operation. The skin incision recommended by this operator differs from the usual one and is planned so as to do the least possible damage to the branches of the facial nerve supplying the orbicularis. The history of one of the cases is remarkable, the operation being undertaken on a woman of 31 to extract the blade of a knife 2¼ inches long and ⅝ inch wide. It had remained with the point lodged in the orbit as the result of an accident in childhood, its presence being long unsuspected, but proved by an excellent skiagram, which is here reproduced.—J. R. Slonaker, the Physiology of Accommodation in the Eye of the Bird. This paper is important to those interested in comparative physiology. One interesting point is that the ciliary muscle of birds, called Crampton's muscle, and also the sphincter and dilator of the pupil are striated, and therefore better adapted for the quick adjustments required in the course of rapid flight through the air than if they were unstriated as in man. Another point is one in which the author differs from some previous observers. He maintains that the ciliary muscle in birds does not act as in man by altering the curvature of the lens, but by a movement of the refracting media along the axis of vision, thus resembling the focussing mechanism of a camera rather than that of the human eye.—In addition to these articles C. F. Charlton discusses the Function of the Lacrymal Secretion from the Point of View of Chemical Physiology; G. H. Burnham relates a case bearing on the Medico-legal Aspect of Blows on the Eyeball in the Region of the Ciliary Processes; S. B. Chase gives a preliminary report on a case of Double Glioma of the Retina which he is treating with radium; C. E. Ferree and Gertrude Rand describe an adaptation of their apparatus for determining visual acuity at low illuminations to the testing of light and colour-sense; T. E. Oertel relates a case of Spontaneous Luxation of the Eyeball; and C. C. Rush gives charts showing the changes in the visual fields after operation for chronic glaucoma.

December: Edward Jackson, Thrombosis of Retinal Veins after Influenza. Two cases in women, aged 59 and 33, are recorded with illustrative plates. In one of them the mass of the hæmorrhage appears to be of the subhyaloid variety. Both patients recovered nearly full vision, and in general, the author remarks, venous thrombosis due to influenza has not the sinister significance of retinal hæmorrhage from some other causes.—H. Friedenwald, Self-inflicted Conjunctivitis. An hysterical girl deceived her doctors by producing a condition of the conjunctivæ which was diagnosed as trachoma. The eye was effectively treated by being sealed under a Buller's shield.—W. L. Benedict, Value of Dental Examination in the Treatment of Ocular Disorders. This paper, from the Mayo Clinic, is of considerable interest. Transmission of organisms from diseased teeth to the eye may happen in one or more of three ways: (1) by direct extension through bone; (2) by the periosteum; or (3) by the blood stream, this last channel being the most usual one. Extraction of teeth does not always yield beneficial results, for it is possible that after extraction a septic pocket may have remained a source of infection. In these cases the use of autogenous vaccines is advocated. Rosenow has shown that organisms taken from diseased teeth are capable of producing disease of the eye when injected directly into the blood stream of animals; and, furthermore, that such organisms have a selective affinity for certain structures of the eye, and that within limitations this selective affinity is characteristic of the strain, and is maintained through several cultural transplants of the organism. Nevertheless the writer believes that the urgency of obtaining surgical cleanliness of the mouth before ophthalmic operation on old people has been overstated, a view that encountered some opposition in the discussion that followed the paper. He also deals with reflex disturbances of the lids and eye muscles relieved by the extraction of decayed teeth.—H. Sewall, Some Optical Imperfections of the Eye and Some of their Uses. This paper is concerned with the effects of light entering the eye through the sclera and the psychological effect of the indirect field of vision on central vision, especially in the matter of colour contrast.—The number includes a report of two cases of Glioma of the Retina, by C. C. Rush; of Malignant Melanoma of the Choroid, with Gradually Decreasing Intra-ocular Tension, by L. M. Francis; of Anomalous Pigmentation of the Skin and Eyelids, by H. V. Würdemann; and of Orbital, Epidural, and Brain Abscess, by M. Blake. The last paper, by J. M. Banister, is entitled, "Hints in Relation to the Dynamics of the Extrinsic Ocular Muscles, with Suggestions as to Treatment of States of Muscular Imbalance."

DANGEROUS DRUGS ACT, 1920:

ISSUE OF DRAFT REGULATIONS.

DRAFT regulations have been issued by the Home Office in regard to the carrying out of the Dangerous Drugs Act which became law last August. Since Sept. 1st, 1920, and pending the issue of regulations under the Act, the restrictions imposed by Dora 40 B have remained in force.

The draft regulations are based upon two Sections of the Act: (1) Section 3, for controlling and restricting the possession, sale, and distribution of raw opium; (2) Section 7, for controlling the manufacture, sale, possession, and distribution of morphine, cocaine, ecgonine, and diamorphine (commonly known as heroin) and their respective salts, and medicinal opium, and preparations and substances containing not less than 1/5th per cent. of morphine or 1/10th per cent. of the other alkaloids.

Manufacture.—In regard to morphine and the other alkaloids enumerated no one shall manufacture them or carry on any process in their manufacture without a licence, except on licensed premises, or otherwise than in accordance with the terms of the licence.

Sale and distribution.—No one shall supply or procure (or offer to do so) raw opium or any of the drugs mentioned for any person whether in the United Kingdom or elsewhere, nor advertise them for sale, unless he is licensed to do so:

Except when the drugs are lawfully dispensed in pursuance of a prescription given by a legally qualified medical practitioner in accordance with certain conditions. Exemptions may be granted for dispensing at public hospitals and on board ship.

Prescribing and dispensing.—The prescription must be in writing, must be dated and signed by the medical practitioner with his full name and address and qualifications, and marked with the words "Not to be repeated," and must specify the total amount of the drug to be supplied on the prescription, except that in the case of prescriptions issued for National Health Insurance purposes on the form provided by the Insurance Committee the medical practitioner's address and qualifications and the words "Not to be repeated" need not be marked on the prescription.

The conditions to be observed by persons, *including any medical practitioner*, dispensing prescriptions for the drugs are:—

The drugs shall not be supplied more than once on the same prescription.

The prescription shall be marked with the date on which it is dispensed, and shall (unless issued for National Health Insurance purposes on the form provided by the Insurance Committee) be retained by the person, firm, or body corporate, by whom the prescription is dispensed, and shall be kept on the premises where it is dispensed.

The ingredients of the prescription so dispensed, with the name and address of the person to whom it is supplied or delivered, shall be entered in a book specially set apart for this sole purpose and kept on the premises where the prescription is dispensed, so that it shall at all times be available for inspection.

Possession.—No one shall be in possession of raw opium or of any of the drugs unless he is licensed to import or export, or to manufacture or supply the drug, or unless he can prove that the drugs were supplied in accordance with a legitimate prescription.

Any duly qualified medical practitioner, or registered dentist, or registered veterinary surgeon, or person employed or engaged in dispensing medicines at any public hospital or other public institution being a person duly registered under the Pharmacy Act, 1868, is authorised, so far as is necessary for the practice of his profession or employment, to be in possession of and supply the drugs.

Labelling.—No one shall supply any article into the composition of which any of the drugs enters in a package or bottle which has not plainly marked on it the amount of the drug in the article, and the total amount in the package or bottle, and in the case of solutions the amount and percentage of the drug in the solution.

Bookkeeping.—Every person who supplies raw opium or any of the drugs, *including any medical practitioner*, shall enter in a book kept for the purpose all supplies obtained by him and all dealings effected by him. Separate books are to be kept for: (*a*) cocaine and ecgonine and substances containing them; (*b*) morphine and substances containing it; (*c*) diamorphine and substances containing it; (*d*) medicinal opium. Entry is to be made on the day on which the drug is received and on the day on which the transaction is effected. A separate book is to be kept in respect of each set of premises. The book shall at all times be available for inspection. No cancellation, obliteration, or alteration is to be made, any mistake in an entry being corrected by a marginal or foot-note.

Pharmacists.—Any person lawfully keeping open shop for the retailing of poisons is authorised:

To manufacture at the shop in the ordinary course of his retail business any preparation, admixture, or extract of any of the drugs;

To carry on at the shop the business of retailing, dispensing, or compounding the drugs, subject to the provisions of these regulations.

In the event of conviction for an offence against the Act this authority may be withdrawn.

Schedules are attached showing the form in which records are to be kept.

BRIGHTON HOSPITAL SUNDAY FUND.—The 1920 collections in the places of worship of Brighton, Hove, and Preston, together with the amounts collected in boxes at hotels and clubs, amounted to £1419 17*s.*, as compared with £1537 0*s.* 8*d.* in 1919. After deducting expenses the Fund has been distributed as follows: Royal Sussex County Hospital, £624; Dispensary, £156; Queen's Nurses, £154; Royal Alexandra Hospital for Sick Children, £130; Women's Hospital, £104; Throat and Ear Hospital, £45; Eye Hospital, £45; Royal Surgical Aid Society, £29 10*s.*; Provident Dispensary, £26; Lady Chichester Hospital for Women, £20; New Sussex Hospital, £15; Sussex County Homœpathic Dispensary, £13; Dental Hospital, £13.

THE LANCET.

LONDON: SATURDAY, JANUARY 15, 1921.

The Hygiene of the Sailor.

THE first sailor required all the oak and triple brass he had around his heart to fortify him against the dangers of his risky enterprise. But he, and HORACE, saw only the menace of the sea, of drowning; little they recked of the hidden dangers of his environment—the causes of sickness were then unrealised. The first cargo vessel on record, the *Ark*, with its huge content and small crew, kept its ship's company on board for 370 days, yet no deaths are reported. In the next famous voyage, made by JASON and the Heracleidæ in the *Argo*, the deaths are due to violence or magic, as we also find in SINDBAD'S stories of his sailings in the Arabian Seas. Disease was in those days of unknown origin, doubtless supernatural, and its relation to surrounding conditions or personal carelessness was masked by the period of incubation, which delayed the outbreak of malaria or typhoid fever until a fortnight after the mosquitoes had begun to worry or the store of water had been renewed. Few general diseases have so constant and arresting a syndrome as small-pox, few so short an incubation as cholera; the origin of these from previous cases was, therefore, early recognised.

Every sailor of the eighteenth century lived a hard life. It was not only in the convicts' galleys that conditions were horrible. Excreta, indeed, could be somehow disposed of in the "head," under the bowsprit, always to leeward of the ship; but the wooden ships leaked, the bilge water and the wood rotting in it filled the ship with a putrid smell; the crowding of the mess decks explains the occasional complaints of officers about the heavy odour rising from the hatchways. Part of the smell was due to uncleanliness; where water was so scarce that a sailor must ask leave of the officer of the watch to get a cupful for a drink, there was little to spare for washing. This, no doubt, accentuated the evils of scurvy and helped to prevent its ulcers from healing. Food at its best was unsavoury; it was also insufficiently nutritious, so the men got scurvy, which lost them their teeth and prevented them from eating what little food there was. Then there were calms to break their hearts, give them fevers with delirium, called "calentures," and drive them overboard to reach the sunny green fields they thought they saw. The only alleviation was the good ventilation they got from the wind coming off the sails in fair weather, which poured down the hatches, blew the ship out, and dried it. The work of the old-time sailors was hard, their voyages uncertain, and when they got back we may be sure they were well pleased with their houses ashore, dark, stuffy, and ill-lighted though we now would think them. So that the sailor got real benefit when in the nineteenth century the era of iron and steam arrived. For he now had a dry bed, as leaks were few, there was no bilge-water and no smell of it; passages shortened and food improved, so scurvy ceased. Iron tanks for water replaced casks, and held more. No longer were there days wasted in the Doldrums; passages became much safer when captains had always a calculable driving power under their hands; and old salts shook their heads and feared there would never be sailors like there had been. Steam and iron widened employment, cheapened food, and increased marriages; vaccination and preventive medicine kept the children alive; so population grew. There was need for more sailors. But the accommodation in ships remained much as it had been, while ashore standards of comfort and of wages rose. Sailors of the better class were hard to get among Englishmen; those who joined were drawn by hunger, or recruited by a boarding-house crimp. Sailors have great difficulty in forming a trade union as they do not live or work together in crowds like miners or cotton-spinners. As they could do nothing to keep up wages, cheaper labour was engaged. Foreigners from poorer countries filled up English ships, content to live and work well and patiently in conditions that few Englishmen, who could keep sober, would face. And owners exploited their seamen, not by any means always or often out of design, but through lack of imagination or knowledge. Is it any wonder that the sailor could not believe the first humane advances of the owners to have any but a purely selfish motive? This is the explanation of the fact that when reforms began they were positively resented by those for whose benefit they were designed. The conditions of the merchant marine roused port medical officers of health, notably two in succession in London—Dr. W. COLLINGRIDGE and Dr. HERBERT WILLIAMS, and Dr. WILLIAMS did succeed in getting the cubic space for sailors in the mercantile marine increased in 1906 from 72 to 120 cubic feet. It is 200 cubic feet in the Royal Navy and 240 in the United States merchant marine. The Sailors' and Firemen's Union, late as it entered the field, has done much, and its work has been reinforced now by the opinion of the Royal Navy, first in Admiral BRUCE SOMERVILLE'S frequently quoted article and now, we are glad to see, by the important Chadwick lecture of the Medical Director-General of the Navy. Sir ROBERT HILL supports the claims of merchant seamen to proper treatment with all the weight of his long experience and high official position. For his help the men of the merchant service owe him deep gratitude.

The needs of sailors in ships fall into three classes. There are first the ships of the Royal Navy, with which must be considered the conditions of soldiers in transports. These have a large scientific staff in charge of them and elaborate statistics to manifest their difficulties. They need not be further considered now. Then there are the large passenger steamers with numerous crews; and last the cargo steamers with small crews, berthed probably on a single deck. If we take the *Olympic* as an example of the second class we find the men are well lodged in warmed airy cabins, with suitable spaces for mess-rooms and lavatories, and good food. It is the smaller ships that cause us anxiety, though we published last week an account of conditions in a United States ship of only 10,000 tons which gives its crew comforts superior to those in any English ship of the size that we have been able to visit. As Sir ROBERT HILL insists, and many port health officers will be in delighted acquiescence, the plans of all ships should be examined and approved by an expert medical officer before their building is begun, and each ship should be inspected and passed, sanitarily, before she goes to sea. Sufficient water should be carried under good arrangements, hot water should be supplied to douches and in lavatories, latrines should be provided with constant flush. There should be a drying-room; every living space should be warmed by radiators; unsheathed, unprotected iron in living spaces should not exist, and there should be artificial ventilation—for a dry ship is a healthy ship. Engine-rooms should be cool; there is just now a promising proposal to seal the engine- and boiler-rooms, and supply all air for the boilers through the engine-room. No sailor should be allowed to have his meals where he sleeps, and hospital accommodation, in isolation, for the sick is necessary. A Seamen's Home in every port will prevent much venereal disease. The mosquito-proofing of a ship in malarial harbours will save much illness. But a card register of the illnesses of all seamen is needed to eliminate the tuberculous, for whom special arrangements must be made at the cost of the owners. Lastly, if the seamen's health is put in the care of the Ministry of Health instead of the Board of Trade, a great deal will have been done to make seafaring an employment fit for the heroes this war again proved so many seamen to be. The report of Dr. J. HOWARD-JONES to the Newport Sanitary Authority, which is reviewed in our columns this week, takes up many of the points on which stress is laid above, and which have been mentioned also in the personal investigations undertaken for THE LANCET on board the ships of various lines.

◆

The Significance of Albuminuria.

THE differentiation of the varieties of albuminuria into those resulting from organic disease of the kidney and those due to some slight disturbance of its function is one of great practical importance. Two noteworthy discussions have taken place on this subject within the last few months—one before the Section of Medicine of the Royal Society of Medicine, to which we have already referred in THE LANCET[1]; the other before the Assurance Medical Society, of which we publish a record in this week's issue. It is interesting to note that the opinion was expressed by several of the speakers that, if the functional or non-nephritic origin of the albuminuria could be established, these cases could be accepted as ordinary risks, provided other conditions were satisfactory. There is now accumulating a great deal of evidence in favour of this opinion, although it must be admitted that before it can be proved definitely by statistical methods careful records of the life-histories of large series of cases must be collected and analysed —the necessary data for which cannot be forthcoming for many years.

Dr. R. HINGSTON FOX, in the careful paper which we publish in full, gave an interesting account of 20 consecutive cases of the albuminuria of adolescents, examined between 1884 and 1896, the average age on entry being 27·7 years. Eighteen of these are known to have lived for an average period approaching 30 years. Fifteen are now living and healthy so far as is known. The most striking fact is that in no case has there been any history of subsequent renal disease. He also drew attention to the fact that Dr. HUGH MACLEAN in his study of 50,000 healthy soldiers in France and 10,000 recruits at Aldershot found albuminuria in 5 per cent., and it appears that of those subsequently attacked with war nephritis the great majority had not shown previous albuminuria. It would seem from these observations that the subjects of functional albuminuria were not specially prone to war nephritis. The general outcome of the discussion was that if a case of albuminuria in a young person, even up to the age of 30, can be proved to belong to the functional or non-nephritic group, and if the case is otherwise unexceptionable, there is little, if any, risk in accepting the life as first-class from the insurance point of view. The difficulty is to establish the position by tests available in ordinary clinical practice or under the still more restricted opportunities of examination for life insurance. The matter is complicated by the fact that though many of the cases belong to the type variously described as postural, orthostatic, or lordotic, there are many other causes of temporary, transient, or variable albuminuria. It does not follow that a test or method of investigation which would demonstrate one of these would be of equal value in all. Indeed, another useful result of the discussion has been the clear demonstration that in the diagnosis of albuminuria from the insurance examiner's standpoint there is no one test, either clinical, chemical, or even microscopical, which can be relied on. An opinion can only be expressed after a careful review of the history, the physique, and general condition of the proposer, the condition of the urine being determined after several examinations at intervals and in some cases after actual investigation of renal function by means of the urea concentration and diastase tests. Dr. HINGSTON FOX gave ten criteria to distinguish what he describes as the albuminuria of adolescents. To these we may refer our readers, as they afford a valuable summary of the methods available. We may draw special attention to the high globulin content of the urine in these cases, which Dr. MACKENZIE WALLIS expresses as the albumin-globulin ratio, but, as we pointed out in regard to a case recently recorded in THE LANCET, this is not reliable by itself, since it has been present in a case of actual renal disease shortly before death. It would seem to be important to take the blood pressure in all of these cases, since it is low as a rule and varies from slight causes. The presence of large numbers of calcium oxalate crystals was a point mentioned by several of the speakers. A warning was also given not to mistake excess of mucin or nucleo-albumin for albuminuria, as is sometimes done. Dr. HINGSTON FOX made some suggestions as to the pathology of this form of albuminuria, but did not mention the work of some Danish observers, which appears to be little known in this country. They claim to have demonstrated by catheterisation of the ureters that the albumin in orthostatic albuminuria comes only from the left kidney, and suggest that it is due to pressure of the ureter on the left renal vein.

The whole subject of functional or non-nephritic albuminuria teems with interest, and still offers a useful field for special investigation. It is now becoming established that certain forms of albuminuria, even in old people, are not of grave import—such, for example, as the condition to which Dr. MACKENZIE WALLIS has applied the name of "leaky kidneys." Such conditions may be of less importance from the insurance medical examiner's standpoint, but they are none the less worthy of study from the point of view of the practitioner of medicine. The attention directed to these points will, we hope, result in further means of differentiating the varieties of albuminuria and appraising their significance.

[1] THE LANCET, 1920, i., 858.

The League of Nations and the Opium Convention.

IN THE LANCET of May 29th, 1920, we sketched the story of the International Opium Convention from its signature at the Hague in 1912, and referred to the bearing upon its effectuation of the Peace Treaties and the League of Nations. At the recent meeting of the Assembly of the League of Nations at Geneva questions relative to the putting into force of the Opium Convention came under consideration and it may be well to indicate the position in which the matter now stands. A valuable memorandum prepared by the Netherlands Government was laid before the Assembly reciting the steps which had been taken by their Foreign Office, in accordance with Article 24 of the Opium Convention, to bring the articles of that Convention into operation. The authors of the memorandum set out that 42 States had signed, and 19 of these had ratified the Convention, while six of the latter had also signed the special protocol of 1914, which bound its signatories to enforce the Convention irrespective of the action or inaction of other Powers. It was further pointed out that under the several Peace Treaties their signatories bound themselves to enforce the Convention as if they had signed the special protocol.

Two other duties had also been confided by the Opium Convention to the Netherlands Government: 1. To act as intermediary between the Powers in regard to interchange of laws and regulations passed by them to restrict the trade in dangerous drugs, as well as of statistical and other information. 2. To arrange for diplomatic communications which might be required in order to arrive at solutions of any difficulties which might arise in giving effect to the Convention. The Netherlands Government were quite willing, if the Assembly approved, that all these duties should be handed over to the League of Nations and its Secretariat. One other question, however, presented itself, and that was that the Powers represented in the Assembly of the League were not identical with those which were parties to the Opium Convention. There were in fact four groups: (1) States which are members of the Society of Nations and also parties to the Opium Convention; (2) States which are not members of the Society of Nations, but yet are parties to the Convention; (3) States which are members of the Society of Nations, but not parties to the Convention; and (4) States which are neither members of the Society of Nations nor parties to the Opium Convention. The whole question as thus stated by the Netherlands Government was referred to Commission II., and on Dec. 15th a report was presented to the Assembly by Mons. JONESCU (Roumania) on the subject. The Assembly unanimously agreed that it would be preferable for the League to undertake the duties placed upon the Netherlands Government by the Opium Convention with regard to the collection of data and the solution of difficulties. The Secretary-General was accordingly authorised to collect information as to the arrangements made by various States for putting the Convention into force. In view, however, of the importance of securing the coöperation of States which have ratified, or who may hereafter ratify, the Convention, but which are not members of the League, the Netherlands Government was authorised to invite their coöperation, and to be the intermediary in regard to those States. It was, moreover, agreed that an Advisory Committee, representative of the countries chiefly concerned, should be set up, and that it should meet as often as desirable. The Assembly further authorised the Council of the League to add representatives to the Committee in respect of such countries not being members of the League which are nevertheless specially concerned in the traffic. An invitation thus to coöperate was to be specially addressed to the United States. The Advisory Committee has been instructed to present its report to the Council three months before each Assembly for submission to the Assembly.

The Dangerous Drugs Act, which was passed by our Parliament before the long vacation, carried out, as far as British legislation is concerned, the statutory obligations of this country. The all-important regulations to be made in order to give effect to that Act have just been issued in a draft, of which we give a précis on p. 134. Much will depend upon the thoroughness with which they are carried out. The question of our self-governing Dominions and dependencies, and especially India, remains to be considered. Slow though the progress has been in securing world-wide supervision of the traffic in these dangerous drugs of addiction, it seems nevertheless to be sure, and the Secretariat of the League will be well advised to expedite further progress with alacrity.

INDICES TO "THE LANCET."

THE Index and Title-page to Vol. II., 1920, complete with the issue of Dec. 25th last, are given in this number of THE LANCET. The Index and Title-page to Vol. I., 1920, were given in THE LANCET of July 10th, 1920.

Subscribers who write from time to time asking for other Indices should note that the Indices for the two Volumes of 1919 were given in THE LANCET on July 5th, 1919, and Jan. 17th, 1920, respectively. None of these Indices has been issued separately from THE LANCET.

Indices for the years 1916, 1917, and 1918 were issued separately, and were not given in THE LANCET owing to the scarcity of paper. Copies of these Indices for the two Volumes of 1916 and for Vol. II., 1917, can no longer be supplied, as the stock is exhausted. Indices for Vol. I., 1917, and for Vols. I. and II., 1918, can still be supplied.

Prior to 1916 the Indices were given, as now, in THE LANCET.

Annotations.

"Ne quid nimis."

FURTHER NEW YEAR HONOURS.

In addition to the honours conferred on New Year's day, knighthoods have been granted to two well-known members of the honorary staffs of Metropolitan hospitals. Dr. Maurice Craig, who received the C.B.E. in 1919 for his neurological work in the field, has been acting as consulting neurologist to the Ministry of Pensions. Dr. Percival Horton-Smith Hartley, who received the C.V.O. in 1912, was on the staff of the 1st London General Hospital, and has been connected with the King Edward VII. Sanatorium since its foundation. Sir Napier Burnett has been appointed a Knight of Grace of the Order of St. John of Jerusalem. We offer our sincere congratulations.

THE TREATMENT OF MALARIA: THE GERMAN EAST AFRICAN EXPEDITION.

In an article on the opening page of this issue Major J. Pratt Johnson and Major Kenneth Gilchrist formulate in a concise and closely reasoned statement the conclusions they have arrived at from a statistical inquiry into the results of treatment and blood examination of a large number of cases of malaria contracted in the course of the campaign in German East Africa. The epidemic appears to have been of severe type, with a large proportion of heavy infections, both with malignant and benign tertian parasites, and the article will well repay a careful perusal. The main features of malaria in East Africa do not appear to be essentially different from those observed during the war in other malarial districts. Thus there is to be found in the article evidence of a growing dissatisfaction with the method of treatment by comparatively small doses of quinine, and the gradual realisation of the good results to be obtained by increasing the dose to at least 30 gr. per day. The advantages of the latter system are seen in a shortening of the average period during which it is found necessary to keep the patients in hospital, and in a substantial reduction in the number of cases in which blood films are found positive on a second examination after an interval of eight days, with a lessened frequency of relapses and a diminished risk of grave consecutive anæmia. The authors found that, in order to attain a given standard of clinical fitness, no longer a stay in hospital was necessary for malignant tertian cases than for those of benign tertian infection; they regard this as due to the fact that the greater initial obstinacy of malignant tertian cases is counter-balanced by the special tendency of benign tertian infections to relapse. On the other hand, cases of combined infection with both types of parasite were more resistant to treatment and needed hospital treatment for a period on the average nearly half as long again in order to attain a similar degree of fitness. Comment is also made on the retarding influence of syphilis, and attention is drawn to the frequency of relapses and severe anæmia in cases where a syphilitic infection is combined with that of malaria. The routine treatment which eventually came to be adopted for cases of ordinary severity was 30 gr. of quinine in solution daily for three weeks, followed by 20 gr. daily for a month, and then 10 gr. daily for two months. No reference is made to the administration of quinine by channels other than the mouth, nor is any distinction drawn between the value of quinine in primary and relapse cases; a note on the experience of the authors on these points would have been of interest. Their statement as to the limitations of quinine treatment, which they describe as being not more than palliative, will receive the sympathetic endorsement of clinical workers in other malarial districts, though an exception might possibly be made in the case of primary malaria treated with larger doses than those stated. An examination of the figures relating to the frequency of relapse shows that the most intractable type of malaria from this point of view is a mixed infection with benign and malignant tertian parasites. Of such cases relapses occurred in a percentage of 39·4. The percentage of relapses in simple benign tertian infections was 23·8, while in malignant tertian infections the relapse incidence was as low as 11·2 per cent. The statistical value of these figures is weakened by the fact that the treatment factor was a varying quantity for individual cases; the average daily amount of quinine administered during the interval preceding the relapse varied from 20·6 gr. to 23·0 gr., and presumably the actual amount given in individual cases varied within even wider limits. The difficulty of securing a constant treatment factor is obvious, but conclusions based on observations in which this condition is not provided for lack precise value; a series of observations on cases receiving identical treatment might have been devised and would have carried greater weight. The views expressed by the authors on the influence of quinine in determining the production of crescent (sexual) forms of the malignant tertian parasite are ingenious, but further observations are needed before they can be regarded as forming more than an interesting speculation. The conditions which determine the production of sexual forms of the malaria parasites are far from being fully understood, and that quinine is one of the factors which may create an environment so menacing to the asexual forms that, through a process of self-preservation, crescents are produced in large numbers is a hypothesis that remains to be proved, though the authors' observations constitute an important addition to the study of the problem.

BACILLARY DYSENTERY WITH MEMBRANE IN THE VAGINA.

Dr. I. I. Lemann has recently reported[1] a complication of bacillary dysentery which does not appear to have been observed previously—membrane in the vagina with œdema of the abdominal wall.

A married woman, aged 48 years, was seen in consultation on Nov. 15th, 1919. On the 3rd she ate a cream puff which did not seem fresh. Severe pains in the epigastrium and diarrhœa began next day. She became so much worse that all food by the mouth was stopped. On examination she had improved, but her face was pinched, the temporal fossæ were sunken, and generally she looked prostrate. The stools were frequent and consisted of extremely offensive bloody mucus. She had vomited only once, though she suffered greatly from nausea. There was marked œdema of the abdomen, which was slightly greater in the right upper quadrant. The liver was felt three inches below the ribs. At the vaginal entrance a roughened corrugated elevation was felt. The vaginal walls and cervix felt œdematous. On inspection with a speculum the elevation proved to be due to a thick, tenacious, dirty-grey membrane, which was pulled off with difficulty, leaving a bleeding ulcer. On the cervix there were an erosion and membrane. Rectal examination was negative. The blood gave a strong agglutination reaction with the Shiga bacillus. This bacillus was cultivated from the vaginal membrane. Microscopical examination of the stools showed pus, blood, and epithelial cells. Treatment consisted in a liquid diet without milk, duodenal irrigations with sodium sulphate solution by means of the Jutte tube, irrigations of the vagina thrice daily with 1 in 1000 permanganate solution. Improvement began almost at once, and the symptoms disappeared in three weeks.

It is noteworthy that the vaginal membrane corresponded exactly with that present in the bowel in dysentery. Thus the bacilli acted on the vaginal mucous membrane in the same way as on the intestinal. How were the bacilli introduced into the vagina? Probably their source was the rectal discharge. This suggestion is borne out by the fact that the inflammation was most intense at the vaginal entrance. In this connexion the view of Flexner and Sweet as to the mode of production of membrane is interesting. They say that the bacilli may abound in the small intestine, where no lesions may be found, but that they give rise to toxins, one of which acts on the nervous system, the other on the lower bowel. The excretion of the toxin causes exudation of lymph into the submucosa, later into the mucosa, leading to ulceration. If the intestinal membrane is produced by excretion of toxins, may not the vaginal be produced in the same way? Another theory is that the infection may have been carried to the vagina by the blood stream. Cases of bacillary dysentery septicæmia have been reported. Of the œdema of the abdominal wall Dr. Lemann can give no explanation. He considers it analogous to the œdema frequently observed on the thoracic wall over empyemata and over abscesses of the liver.

[1] Journal of the American Medical Association, Dec. 18th, 1920.

DR. BEATTIE CROZIER: MEDICAL PHILOSOPHER.

THOUGH it was neither in the practice nor in the scientific advancement of medicine that Dr. Crozier achieved his fame, his training had a profound effect on his subsequent activities. While in his early youth he derived inspiration from the study of phrenology, his medical studies directed his reading into more scientific channels, and the study of books by Darwin and Spencer altered his whole scheme of life. On his qualification at the University of Toronto in 1872 he decided to leave Canada, where he was born and had always lived, for England, where he settled nominally as a medical practitioner. His real work, however, rose out of his search among the philosophers of all ages for a school of thought which would satisfy his own aspirations while harmonising with some of the then new teachings of Herbert Spencer, whose materialistic outlook he could never accept. The middle period of his life Crozier spent in the study of the history of intellectual development, and his book on this subject, published in 1897, was an attempt to show that the laws governing the rise and fall of philosophies could be interpreted, and that at least some guidance for the future could be obtained by their study. In his later years, though his failing eyesight made work difficult, he thought and wrote on political economy. His final publication in 1917 was a survey of the economic, intellectual, and religious movements brought into being or influenced by the war. Dr. Crozier had a definite position in a field of thought not generally entered by medical men, and his high ideals and laborious efforts to further our national progress remain on record in his works.

STEPS TOWARDS BIOLOGICAL STANDARDISATION.

RECENT discussions on the best means of ensuring accuracy in dispensing have ignored the most important and probable source of danger in therapeutic agents administered to the public—that which is due to lack of standardisation and is beyond the control of the dispenser. Modern therapeutics has largely substituted for older drugs biological preparations, alkaloids, vaccines, and complex synthetic preparations which are not amenable to ordinary chemical tests. The need for the establishment of biological standards of measurement and of means for their ready application has been seen and emphasised by the Medical Research Committee since its formation in 1914. But the large amount of ultimate quantitative research required could not be undertaken in the war years except in so far as certain arbitrary standards of measurements had to be established at short notice, as, for example, those applied to salvarsan compounds sold in this country. At the end of 1916 the Committee issued a memorandum to the Government again urging the desirability of setting up official standards of value and authenticity for arsenical biological preparations, serums, and the like used in medical practice, and expressed the opinion that the absence of possibilities of control was not only discreditable to our national position in the world of science but a source of grave danger to the community. The Medical Research Committee urged strongly "the establishment of a Government laboratory for biological standardisation as needed for national purposes no less important than those of an analogous kind fulfilled by the National Physical Laboratory." A fuller statement of the need for such a laboratory was issued early in 1919, and various research schemes in preparation for its establishment have been centralised at the National Institute for Medical Research at Hampstead. A special committee on Biological Standards and the Methods of Biological Assay, consisting of Professor W. Bulloch, F.R.S., Dr. H. H. Dale, F.R.S., Professor G. Dreyer, Sir Walter Fletcher, F.R.S., and Professor C. J. Martin, F.R.S., has been appointed by the Medical Research Council to advise them on the promotion and coördination of studies of this kind. Moreover, Dr. Dale has been appointed to represent the Council on the Departmental Committee appointed last April[1] to advise the Minister of Health in the administrative and legislative measures that may be necessary. The report of this Committee should be issued shortly. Meanwhile, since the work in departments of bacteriology and pathology, biochemistry, and pharmacology at the National Institute is daily concerned with quantitative standards, the Council has invited Dr. Dale to serve as director of a Biological Standards Department. This department will have special relation to the central administrative organisation and supply of the separate departments of the Institute, and will, it is hoped, bring effectively into touch all the work likely to have a useful application to a national system of standardisation. For this the National Institute would seem to afford an appropriate permanent home.

GAS AND OXYGEN IN OBSTETRICS.

THE National Anæsthesia Research Society of America has issued a monograph on nitrous-oxide-oxygen analgesia and anæsthesia in normal labour and operative obstetrics. The publication is remarkable for several reasons. Its form is unusual, being more that of a presentation poetry-book than that generally associated with scientific productions; since this includes good paper, large clear type, plenty of space, and ornamental captions it is only to be commended. The matter is fairly comprehensive, including an account of the physiological actions of anæsthetics on pregnant animals and of blood changes due to various anæsthetics. At the same time there is a lack of definite practical details in the account of the applications of nitrous oxide analgesia to patients in labour. With the arrangements commonly in vogue in this country, where labour is conducted on a bed, and with the apparatus usually employed, nitrous oxide and oxygen is an extremely inconvenient anæsthetic. The patient's head is some distance from the edge of the bed and half immersed in a pillow. Doubtless our American confrères, who have employed nitrous oxide in labour far more freely than we have, have found means to increase its facility. A description of them would greatly have enhanced the practical value of this monograph. It is claimed for nitrous oxide that, so far from lengthening labour as other anæsthetics are accused of doing, it actually shortens the process. This is owing to the fact that during analgesia the patient will effectively coöperate. She is encouraged to assist the contraction of the uterus, and since this is prevented from giving her pain, she finds no obstacle to bearing down. Although self-administration of nitrous oxide and oxygen for the purposes of analgesia is possible, and has been often permitted by some of the writers, yet it seems clear that the use of this anæsthetic for labour necessitates the presence of a second medical man. Certainly this is the case if all the advantage possible is to be got from this particular agent. It may well be, indeed, that, as is suggested in the monograph, an ideal labour would be conducted through the presence of a skilled anæsthetist supplying the analgesia of nitrous oxide and oxygen for the pains of the first and the early part of the second stage, and full anæsthesia by the same drugs for the rest of the process. The baby is unaffected in ordinary labours conducted under nitrous oxide and oxygen.

---

[1] THE LANCET, 1920, i., 974.

PRIMARY MESOTHELIOMA OF THE PLEURA.

ACCORDING to Dr. Ernest S. Du Bray and Dr. F. B. Rosson,[1] of the University of California Medical School, who report an illustrative case, primary tumours of the pleura are of very rare occurrence, being considerably less frequent than primary growths of the lungs or bronchi. Patterson, in 1909, reported two personal cases and collected 96 others from the literature, but some of these could not be considered authentic owing to the incompleteness of the data. The disease occurs twice as frequently in men as in women, and the greatest number of cases are found between the ages of 30 and 40. It is a little commoner on the right side than on the left, but it may be bilateral. The origin of these tumours is still obscure, as it has not been decided whether they arise from the lining cells of the pleura or from the intima of the lymphatics. The writers are in favour of a mesothelial origin, and therefore prefer the term mesothelioma to carcinoma, although most of these tumours have been described under the name of endothelioma. The onset is usually insidious and the course progressive, the average duration of the disease being from six to nine months. Pain in the chest, which is usually severe and persistent, is the earliest and most significant symptom. The physical signs are in no way pathognomonic, but a persistent, rapidly reaccumulating hæmorrhagic pleural effusion is suggestive. The temperature usually remains normal throughout the disease, only exceptionally is there a slight evening elevation, which is usually due to a superimposed pulmonary infection. X ray examination does not afford much help in the diagnosis, but merely shows a massive pleural effusion in the great majority of cases. Cytodiagnosis is of very limited value, as numerous observers have found that in many cancerous pleurisies cancer cells are not present in the transudate, or, if present, are very difficult to recognise. Chemical study of the pleural effusion is also of little value. The most important and difficult diseases to exclude are pulmonary tuberculosis with hæmorrhagic pleural effusion and primary malignant disease of the lungs and bronchi. In a case which occurred in a physician, aged 40, the diagnosis made during life of tumour of the left pleura with extension into the lung and peritoneal cavity was confirmed by the necropsy.

MID-BRAIN LOCALISATION.

IN the current number of *Brain* Dr. S. A. Kinnier Wilson makes another of his masterly contributions to our knowledge of localisation in the central portions of the brain, recalling his former work on the symptomatology of the putamen, which led to the acceptance of a new symptom-complex—lenticular degeneration. In the present article he correlates the clinical findings in cases where cortical control is partially or completely removed, with the results of experiments by Professor C. S. Sherrington and others designed to effect this removal. The result of his investigation may be summarised as follows. When cortical control is removed completely from the rest of the nervous system by experimental or natural lesion the body and limbs assume a characteristic attitude; the limbs become rigidly extended, the hands become extensor-pronated, there is some degree of opisthotonus and retraction of the head. Further, the removal of cortical control may be (*a*) incomplete or (*b*) intermittent. In the former case the resultant attitude will present only partially the postural features of decerebration, while in the latter there will be temporary accentuation of those features—i.e., the occurrence of tonic fits due to "attacks of decerebration." A critical analysis of the records of experiments leads Dr. Wilson to the provisional conclusion that the red nucleus, with its cerebellar, thalamic, and spinal connexions, is the "centre of this attitude or posture-producing mechanism." Further, that the "decerebrate attitude of mesencephalic origin is maintained by afferents reaching its source by spino-cerebellar paths and inhibited by stimulation of a ponto-cerebellar path via the neighbourhood of the vermis." Review of clinical material in the light of this theory results in simplification of exceedingly diverse phenomena. Tonic spasm in submeningeal or intraventricular hæmorrhage, meningitis, hydrops ventriculi, the well-known "cerebellar" attitude, the characteristic position of the hand in chorea, in athetosis and in hemiplegia, opisthotonus in tetanus, and even in hysteria are thereby all reduced to their common denominator—decerebration, complete or partial, permanent or temporary. The starting point of the train of thought was a passing allusion by that seer of neurology, Hughlings Jackson, to what he called "tetanus-like seizures" and "fragments of the tetanus-like condition." It appears that Dr. Wilson has succeeded in discovering for us the underlying significance of yet another of Hughlings Jackson's flashes of insight, many of which were given to the medical world in our columns under the general title "Neurological Fragments."

PHYSIO-THERAPEUTICS IN AMERICA.

THE noteworthy feature of the meeting of the American Therapeutic Association, reported in our present issue, was the importance ascribed to physiotherapy by those who contributed papers and took part in discussions. Treatment by electrical methods formed the subject of the greater number of the papers. Four authors contributed papers on actinotherapy, and treatment by radium needles was considered in one paper. Only in five contributions was treatment by methods other than physical proposed. Various standing committees presented reports at the meeting conveying suggestions and recommendations regarding the uses of various physio-therapeutic agents, including the direct current, rhythmic currents, mechanical vibration and exercises, and hot and tepid baths. No entirely new or previously untried physio-therapeutic method was described, but there were some interesting contributions which will attract the attention of workers in physio-therapy in this country. One of these deals with the use of diathermy and the galvanic current for treatment of occlusion, partial or complete, of the cerebral vessels. In another the slow sine wave alternating current is recommended for the treatment of fæcal impaction of the sigmoid flexure; Dr. F. H. Morse maintained that symptoms which were often attributed to catarrhal salpingitis, uterine displacement, or hæmorrhoids, were frequently the results of sigmoid impaction. The treatment of inflammation of the bladder, uterus, and sigmoid flexure by injecting them with argyrol and then passing the galvanic current through the inflamed parts was described by Dr. C. S. King, who claimed that better results could be obtained by the combined treatment than by either method singly. Treatment by diathermy seems to be increasing in popularity; the contributions on this subject dealt with the non-surgical uses of diathermy. The use of electrical methods for obtaining mechanical effects, such as contraction of muscle and the removal of inflammatory products, formed the topic of other contributions. Apart from the good results obtained, the use of electricity for the various diseases considered at the meeting appears to be rational and applied in the endeavour to obtain known chemical and physical changes and procure therapeutic results by means of these changes.

LORD CAVE is to preside over the committee appointed by Dr. Addison to enquire into the financial position of the voluntary hospitals.

DR. CONSTANTIN DANIEL, Professor of Pathological Surgery at the Faculty of Medicine of the University of Bucharest, has been transferred to the recently created chair of clinical gynæcology.

DR. CYRIL HARTLEY DURRANT, chief medical officer to the Presidency of Saint Christopher and Nevis, has been appointed an official member of the Legislative Council of that Presidency.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Health of Belfast.

Dr. H. W. Bailie, medical superintendent officer of health, has published some figures dealing with the health of the city to Nov. 27th, 1920. The total deaths numbered 7450, as against 7278 in the previous 12 months, representing a death-rate of 18 per 1000, as compared with 17·9 in 1919. The deaths from phthisis show a substantial reduction in the previous year, the total being 774, a rate of 1·9 per 1000, as against 853 deaths, a rate of 2·1 per 1000, in 1919. This rate is the lowest recorded in Belfast since regular records were available. In 1899 the rate was 3·2 per 1000. The fall began in 1907, when the rate was 2·5 per 1000. There was a continuous fall until 1912, when the rate was 2 per 1000. From 1915 the rate steadily increased for three years, being 2·17 in 1916, 2·4 in 1917, and 2·7 in 1918 (the influenza year). The decline in 1920 is substantial and affords ground for congratulation; it shows that the antituberculosis crusade has not been in vain. Scarlet fever still continues very prevalent, the number of cases in 12 months being no less than 2334, as compared with 2793 in the previous 12 months. The disease continues to be of a mild form, but the attempts to check its excessive prevalence have been unsuccessful. There were 291 cases of diphtheria notified, 218 of typhoid, and 187 of erysipelas, as against 234, 110, and 149 respectively in the previous year. The deaths from zymotic disease totalled 749, representing a rate of 1·8, as against a rate of 1·5 in 1919. Infant mortality continues high. The rate was 130 per 1000 as compared with 113 in 1919, 144 in 1918, 130 in 1917, and 113 in 1916. These figures are disappointing in view of the considerable efforts put forth in Belfast to protect child life in the form of babies' clubs, ante-natal clinics, &c. The large amount of female employment is no doubt a factor. All the evidence goes to show that the most fundamental factors in reducing infant mortality are good mothering and attention to the diet and hygiene of the infant. In many counties in Ireland the infant mortality-rate is from 60 to 70 per 1000—one of the lowest rates in the world—in spite of a relatively low standard of housing and material comfort. Mother-care is the explanation. Large cities everywhere take a large toll of infant life, more especially when many avenues of employment are open to women.

"*83rd (Dublin) General Hospital.*"

The annual dinner of the Dublin unit of the 83rd General Hospital was held on Jan. 8th at the Royal College of Surgeons, under the chairmanship of Sir William Taylor, who, nearly five years ago, while President of the College, organised the unit. The members had as their guests General R. H. S. Sawyer, late A.M.S. (retired), who, during the greater part of the time the unit worked at Boulogne, was D.D.M.S. of that area, and Mr. Alfred Miller, the Registrar of the College. Mr. Edward Taylor, the present President of the College, himself a member of the unit, was kept away by illness, but nearly all the other members of the unit were present, and a pleasant evening was spent, reminiscent of the happy comradeship which existed while the unit was on active service. General Sawyer, as the immediate authority of the service in touch with the "83rd General Hospital," spoke highly of the medical and surgical work performed in the well-known huts overlooking the harbour at Boulogne.

The late Dr. John F. Knott.

By the passing away of Dr. John Knott on Jan. 2nd Dublin medicine has lost one of its most interesting figures, and the world of medical literature a prolific and racy writer possessed of an extraordinary knowledge of the history of medical science. After a distinguished career in the school of the Royal College of Surgeons and in Trinity College, and after visiting many continental centres, Dr. Knott settled in Dublin a generation ago as a private medical tutor or "grinder." Many of the most distinguished Dublin students of the "eighties" passed through his hands. He edited the third edition of Mapother's "Human Physiology," and he contributed largely to the periodical literature any time this 40 years, choosing topics usually from medical history. He made particular studies of the final illnesses of Lord Byron and of Napoleon. He had little belief in modern developments of medical science, and loved to have a tilt at such orthodox doctrines as that of the bacterial origin of infective disease. He was a great lover of books, and he must have left a valuable collection.

SWITZERLAND.

(FROM OUR OWN CORRESPONDENT.)

The Medical Profession and the Sickness Insurance Unions.

THE relations between the medical profession and the sickness insurance unions is a subject which gives rise to much anxiety in our medical world. Sickness and accident insurance now covers a very wide field, but not in the same proportion in different parts of the country. In Geneva and Lausanne, with their highly individualistic populations, the sickness insurance unions are not nearly as popular as, for example, in Zurich and Basle. In Basle, which has 140,000 inhabitants, over 100,000 are members of the unions; these include the whole of the working class and a considerable part of the middle classes, and thus only some 30,000 people remain under private practice. As the Swiss Federal Insurance Act stipulates the free choice of doctor, practically all practitioners of the towns are attached to these unions, and, in fact, many are drawing their chief income from them. Up to the end of 1920 the fees were Fr. 1.50 for each consultation in the practitioner's house and Fr.2.50 for each visit. Now the charges are Fr. 2 and Fr. 3 respectively. Of the different sickness insurance institutes in Basle the Municipal Sickness Insurance Society is the strongest, as it is subsidised with public funds. The monthly premium is Fr.2.50. But according to the income of the member this premium is partly or wholly paid by the State. Of 66,000 members, 14,000 only pay the full premium. The members have the right to free medical treatment, including drugs, hospital, and sanatorium charges. The average cost of each member to the society is Fr.23.70. With the high cost of living and the very low premiums it is probable that more and more people will join the societies which are becoming increasingly powerful, and the decrease in private practice making the great mass of the practitioners entirely dependent on them. The whole system of sickness insurance is therefore being critically scrutinised by the profession.

For the discussion of all these questions a special weekly paper has been founded. The *Schweizerische Aerztezeitung für Standesfragen* (*Bulletin Professionel des Médecins Suisses*) is edited under the authority of the Executive Council of the Swiss Medical Association, and appears both in German and French. It is sent free to every practitioner in the country. Such an organ is doubly wanted, as a new Bill covering State insurance against old age and invalidity will soon be brought before Parliament. At the same time the old organisation of sickness insurance is awaiting revision, and it is highly necessary that the profession should have a voice therein. As Dr. Haemig, of Zurich, has recently pointed out in a well-documented article in the *Schweizerische Medizinische Wochenschrift*, sickness insurance has its very serious drawbacks. Dr. Haemig draws his conclusions from statistics of the Bricklayers' Insurance Union of Zurich. In 1894 the average member of the union had annually four and a half days' of incapacity for work; in 1913, however, 13 days; and in 1917, 13. Influenza renders the statistics of the follow years useless for comparison. In 1895, out of members. 25 were recorded as incapable of work; in 1913 more than 80; in 1917, 66. In the same period the claims on the fund arising from chronic diseases like tuberculosis or heart disease showed a decrease. The steady increase is due to more trivial ailments like pharyngitis, wax in ear, and so forth. This makes it clear that on the one hand the members, with gradually increasing frequency asked their doctor to certify them unfit for work, and, on the other hand, the doctors became more and more generous in notifying members as incapable of work. Such conditions have very serious economic consequences for the unions, and, further, they have a very deplorable effect on the psychical state of the people; ultimately they are apt to destroy in neurasthenics the incentive to work. Dr. Haemig sees the remedy first in the formation of a neutral control board and next in the insertion of a clause in the new Act that the daily insurance pay must in all cases be below the daily wage.

The Swiss Neurological Society.

The Swiss Neurological Society, under the chairmanship of Professor Robert Bing, recently held its annual meeting at Basle. The relation between the nervous system and internal secretion was the chief topic discussed. From the many other communications we may select for comment the studies of Professor Landau (Berne) on the brain of Gambetta preserved in Paris. It had been commonly stated that the brain of the great French patriot was abnormally small—only 1180 g. Landau found this to be false, the apparent small size being the effect of technical errors in its conservation. On the other hand, it appears that the centre of speech is enormously developed, an interesting fact, as Gambetta was notoriously lacking in the gift of oratory. Professor Hotz, director of the surgical clinic, spoke of the operation of sex-gland implantation, the so-called operation of Steinach, which has recently been advertised in the press. His experiments led Hotz to an entirely negative opinion, as he observed none of the results recorded by the originators of that operation.

Jan. 7th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENTS.)

Venereal Diseases among Women.

THE large amount of venereal disease in India and the frequency with which it is responsible for gynæcological trouble has been suspected for some time. The council of the Countess of Dufferin's Fund recently caused an inquiry to be made to discover how far this suspicion was correct and how far facilities for efficient treatment existed in women's hospitals. The result of the inquiry elicited the almost unanimous opinion of the medical men and women consulted that venereal disease was responsible for a very large proportion of gynæcological disease and a considerable proportion of the high infant mortality in India, and that facilities for modern treatment (at least in women's hospitals) were few indeed. The council then applied to the Government of India for a grant to enable it to organise post-graduate courses of instruction for medical women in the modern treatment of venereal disease. It also asked that medical women who had attended these or similar courses should be allowed to purchase necessary drugs from Government stores at reduced rates, and to have necessary pathological investigations done free of charge at Government laboratories. These proposals have been acceded to by the Government, and courses of instruction have been held at Deolali under the superintendence of Lieutenant-Colonel G. H. Frost, I.M.S., consulting dermatologist to the Government of India, during March, 1920. The courses last 12 days, and are well attended by medical women. The syllabus includes lectures, clinical demonstrations, instruction in the newer method of treatment, and a considerable amount of practical laboratory work. Courses for the coming year are now being organised, including two for medical women of the assistant-surgeon class.

Medical Aid in the Punjab.

In the triennial report on the Working of the Charitable Dispensaries in the Punjab for the years 1917, 1918, and 1919 it is stated that owing to the dearth of trained workers arrangements for medical relief in the Punjab are far from satisfactory. The report pays a tribute to the Punjab Medical School for Women, which is incorporated with the Woman's Christian Medical College, Ludhiana, and is the recognised Government school for the training of women for a medical career. This institution has continued to supply trained workers for employment in women's hospitals and dispensaries so far as it was in a position to do so. The number of non-medical students is still small, although the teaching and hostel arrangements leave nothing to be desired. Plans are under consideration for rebuilding the institution.

First Aid in Madras.

The executive council of the St. John Ambulance Association, Simla, has requested the assistance of the Madras Chamber of Commerce with regard to the formation of regular ambulance divisions for practical work in the mills and factories in the city. The Chamber has replied that classes in first aid have already been opened in several mills and have proved very successful, and that the movement will have the sympathy and encouragement of the Chamber.

Tibet Mission Medical Officer.

In response to several requests by the Dalai Lama and his Ministers that a British officer might be allowed to pay a friendly visit to Lhasa, the Government of India are sending Major R. S. Kennedy, I.M.S., as senior medical officer of the Mission.

AMERICAN THERAPEUTIC ASSOCIATION.

THE thirtieth annual meeting of this association was held in Atlantic City from Sept. 14th to 17th, 1920, with Dr. WILLIAM MARTIN, the President, in the chair.

Dr. EDWARD C. TITUS and Dr. FREDERIC DE KRAFT of New York read a contribution on the

Employment of Diathermy and Galvanism in Management of Sequelæ of Occlusion, Partial or Complete, and Rupture of Cerebral Arteries,

in which they referred to a report on the use of diathermy as an adjunct in the treatment of chronic syphilis published by them in the *International Journal of Surgery*. In this report they showed that there was induced a marked heating of all the tissues, followed by active hyperæmia, stimulation of the metabolic processes and increased elimination, local and general, profuse diaphoresis, and augmented secretion of urine. The conditions produced in the tissues were conducive to absorption of inflammatory deposits irrespective of their character. Later results had been equally satisfactory in various syphilitic manifestations. Extensive experiments with galvanism had shown that it improved the nutrition of the coats of the blood-vessels as well as of the surrounding tissues, and beneficially modified vascular tone. It would thus be seen that by the combined use of diathermy and galvanism effects were obtained which could not be derived from the application of either of the currents individually. During the past four or five years they had employed this combined method to remove as far as possible the results of cerebral hæmorrhage or embolism, also in cerebral endarteritis, nervous breakdown, and cerebral neurasthenia, due to impaired nutrition of the brain because of deficient circulation. The method used was as follows: An electrode, 2 by 4 inches, or slightly larger, was moulded to conform to the contour of the forehead. Under this electrode, in direct contact with the head, were placed 30 layers of surgical gauze, saturated in salt solution. The gauze pad was slightly larger than the metal electrode, so that none of the bare metal touched the skin. The electrode was then securely fastened over the gauze by means of a roller bandage and connected to the negative pole. The patient was then placed on a suitable table while the current was administered. A second electrode similar in size and construction to the one just described was placed on the neck just below the line of the hair. This electrode was connected to the positive pole and held in position by a suitable pillow. A current from a battery had proved the safest and most suitable for galvanisation of the brain. If a wall cabinet current was used it should have a volt-meter as well as a milliamperemeter. It was always well to begin with a mild current, about 1 to 3 milliamperes and 5 volts, and the current should be turned on and off slowly. The strength of the current with the low voltage (5) might be increased slowly to 10, 20, or even 30 milliamperes. The results of this galvanisation were better and more rapid if it was preceded by diathermisation of the brain, which seemed to prepare the way for the galvanic current by improving the circulation and the lymphatic flow.

Dr. FRED. H. MORSE presented a paper on

Sigmoid Impaction: Its Significance, Pathology, and Treatment,

illustrated with lantern slides. He stated that the sigmoid flexure was a field that urgently demanded relief. Dr. Morse was confident that many patients being treated for cystitis, prostatitis, hæmorrhoids, uterine displacements, and so-called catarrhal salpingitis were really suffering from displacement of the pelvic colon. If the distortions and bends with which we had to deal in sigmoid impaction and the conditions about the splenic flexure and descending colon were to be treated successfully, therapeutic effort must be carefully guided with a view to the effect desired. Direct rectal application must be made to the seat of threatened obstruction, and this could be done safely and intelligently since the use of the alternating current had been brought under control. A large amount of muscle stimulation could now be used without any possible harm to the inflamed mucous membrane. The results demonstrated on the screen, the speaker declared, were not merely hypothetical theories but legitimate clinical realisations.—Dr. CORA SMITH KING and Dr. ELNORA C. FOLKMAR both testified to the value of Dr. Morse's technique.

Dr. ELNORA CUDDEBACK FOLKMAR presented a communication on

Diathermy as a Therapeutic Agent, Especially in the Treatment of Sprains, Fractures, Adhesions, and Chronic Stiff and Painful Joints.

She stated that a therapeutic measure for the purposes of this paper was defined as one which aided nature on her own plan to restore physiological function which for some reason nature had not been able to initiate, or did so only in a feeble way. Diathermy was such an agent. Nature's cardinal method of restoration was the production of heat—inflammation locally, fever systemically. No injury, whether traumatic, chemical, thermic, or bacterial, could be recovered from except through the agency of heat, whether the heat originated within the system or was induced by external agents. Diathermy increased the temperature of the tissue, dilated the blood-vessels by direct influence, and increased the blood-supply to the area treated; it quickened the chemical processes of metabolism, and thus aided nature in making a cure. It relieved pain and tenderness by relieving pressure from exudates; it softened tissues and made them better conductors of low-frequency currents and more susceptible to mechanical treatment, such as vibration and massage. Dr. Folkmar described in detail the technique of diathermy as applied in the treatment of trauma, visceral adhesions, and chronic, stiff, and painful joints. She followed diathermic treatment with a surging faradic massage, and then gave what she had called the "faradic grip," which consisted in slowly moving the secondary coil over the primary until the patient gave an involuntary sound. This was repeated five or six times, and was followed by passive and active attempts at motion. Diathermy was destined to become quite as important to the orthopædist as splints and bandages. The odontologist must call on diathermy to assist nature in repair processes, as he now called on radiology to confirm his diagnosis. The surgeon must use diathermy in his fracture cases to promote rapid union and to relieve pressure and pain, and must take cognisance of diathermy as a valuable agent for the preliminary and subsequent treatment in pelvic and abdominal operations to prevent the formation of adhesions. The layman already demanded an X ray as a confirmatory diagnosis. He would soon demand diathermic treatments.

Dr. WILLIAM L. CLARK read a paper on

The Rôle of Radium Needles in the Treatment of Malignant Disease.

He described his early experiments in attempting to devise radium needles that would be suitable for the treatment of malignant disease. He was told that the secondary rays from the needles would produce necrosis and sloughing. On investigation he found it quite true that sloughs were formed from the secondary rays in dry skin, but in malignant disease this did not occur unless the exposure was too prolonged. This was explained by the fact that in malignant disease the moisture around the needles absorbed the secondary rays. Unless the tissue was very much devitalised, one could leave the needles in for 24 hours without causing sloughing. Radium capsules and plaques had a distinct field of utility, but the needles had made many things possible which were not possible without their use. The removal of a malignant growth from the mouth and of metastatic glands in the neck was pure folly because the migratory cells were not taken into account. The migratory cells in the ducts should be treated, not necessarily with the needle, because they might be reached by the element properly filtered. The needle might be inserted right into the gland, which was absorbed, inhibited, retrogressed, and disappeared. Where the glands had broken down it might be possible to excise them and then insert a radium tube. They had had cases treated in this way in which they appeared to have inhibited malignant conditions. Lantern slides were exhibited showing the use of radium needles in cancer of the stomach following gastro-enterostomy, squamous epithelioma of the lip, and a malignant growth of the mastoid region which when treated with the radium needles showed regression without great destruction. Results were also shown in other malignant conditions.

Dr. CORA KING read a paper on

The Continuous Current in Inflammatory Conditions.

She spoke more particularly of inflammatory conditions of the sigmoid, bladder, uterine endometrium, and the cervical and vaginal membranes. In the treatment adopted by her the sinusoidal current was used, with one pad under the sacrum and the other over the abdomen, as strong as the patient could comfortably bear it. When the muscles were well synchronised, with the bulb in the rectum but without a rectal tube, a bland soapsuds enema was given. In the proper posture gravity would carry the fluid to the transverse colon. After the patient had evacuated the enema she was placed in the knee-chest position, and two drachms of argyrol, 25 per cent., were introduced into the rectum. The uterus was then tamponed with 25 per cent. argyrol, and if there was bladder trouble argyrol was introduced into the bladder. The patient was then placed in the dorsal decubitus, and large pads were placed across the pelvis, low down over the pubic bone. The galvanic current was then passed to easy tolerance, three to five milliamperes, gradually raised to ten milliamperes in the course of 18 to 20 minutes. Dr. King considered that uterine inflammatory conditions, when not gonococcal in origin, were mostly due to extension of inflammatory conditions in the colon. At any rate, under this treatment the patients made remarkable improvement. Dr. King said she had used argyrol and the galvanic current separately, but neither alone gave the results that were obtained by this combination.

Public Health.

REPORTS TO SANITARY AUTHORITIES.

Newport Port.

IT is possible that our national system of supervision of the housing of seamen is, in part at least, responsible for the defective conditions far too frequently found on our merchant vessels. The whole question is very ably discussed by Dr. J. Howard-Jones in his 1919 annual report to the Newport Port Sanitary Authority. The Board of Trade is the department responsible for the supervision of the design of ships, including those parts of the vessel used for the accommodation of the crew. Without wishing to criticise a Government department that has done excellent work in many directions, we agree with Dr. Howard-Jones in thinking that the Board of Trade has not yet fully realised the great importance of marine hygiene, as vessels are still being built on which the accommodation provided for the crew is ill-designed and in many respects unsatisfactory. Often great improvement could have been effected by alteration of the design before the vessel was built, and such alteration would, in many cases, not have involved much, if any, increase in the cost of construction. Dr. Howard-Jones states that the crew spaces provided by some shipowners are far in advance of the requirements, and even of the recommendations of the Board of Trade, while many vessels which have recently been certified by the Board of Trade contravene the regulations of that department in many particulars. The present regulations of the Board of Trade are, in Dr. Howard-Jones's view, too indefinite, with the result that builders interpret them differently. In the past the British standard has been accepted by most nations, but some of them are now demanding in many respects a higher standard of hygiene, and the progress in Britain has not kept pace with that made in some maritime countries of Europe. In regard to cubic space the British minimum is 72 cub. ft. and 12 sq. ft. of floor space per man, where wash-houses and mess-rooms are provided, whereas the Norwegian, Swedish, and Australian authorities require no less than 140 cub. ft. and 18 sq. ft. floor space. Again, the British regulations require a sufficient height in cabins for men of ordinary stature to stand and move about in an upright position—that is to say, at least 5 ft. 6 in. between the floor and under surface of the beams. No provision is made for the comfort and convenience of taller men. They must accommodate themselves to the height of the quarters or remain on shore, where they are provided with bedrooms not less than 8 ft. in height.

The accommodation for seamen on board Scandinavian and American vessels is often far superior to that on the average British ship. In this connexion Dr. Howard-Jones gives an instance which recently came under his observation in which a British firm of shipbuilders built two vessels, one for a Norwegian and the other for a British company. He supplies details of the accommodation for the crew on the Norwegian and British vessel respectively, the former being in nearly every respect much superior to the latter.

Dr. Howard-Jones expresses the view that the control of shipbuilding by the Government of this country is carried on in a very unsatisfactory manner in so far as marine hygiene is concerned, and, in support of this contention, he alludes to the fact that the evils to which he has so frequently drawn attention in his annual reports are still being perpetrated without interference by the Board of Trade. It should be understood that vessels entering our ports in the ordinary course of trade are subjected to regular inspection by the medical officers of health and sanitary inspectors employed by the port and riparian sanitary authorities, with a view to the detection of conditions prejudicial to the health of the crews. Much excellent work has been done in this connexion and minor defects such as the lack of adequate ventilation or faults arising from disrepair, are generally at once rectified when brought to the notice of the shipowners or their agents. But, where much structural alteration is required in order to remedy the defects found, it is difficult for the officers of the port sanitary authority to take effective action, more especially in the case of a British vessel which has been certified by the Board of Trade as complying with their regulations. In such circumstances, the shipowners might very properly object to carry out the requirements of the Port Sanitary Authority on the ground that the vessel conformed in all respects with the regulations of the Government department responsible for the supervision of the design of British vessels. Obviously the proper time to draw attention to such defects is not after the vessel is built, but before she is built; and, if satisfactory results are to be obtained, it is essential that detailed plans of the officers' and men's quarters should be submitted for approval to persons possessing extensive knowledge and experience of marine hygiene previous to the construction of the vessel.

Dr. Howard-Jones makes some valuable suggestions with the view of remedying the existing state of affairs. He points out that the Ministry of Health was established to coördinate and improve public health administration in the country, yet supervision of the housing of seamen on board ship has not been included among the present duties of the Ministry. Marine hygiene is essentially an international question, and there would be much advantage if international standards were established. He also gives details of the improvements which he would like to see introduced in officers' and men's quarters on board tramp steamers. As these are the result of many years' patient study of the subject, they should receive the careful consideration of all interested in the welfare of our merchant seamen.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

County Palatine of Chester.

IN his annual report for the year 1919 Dr. Meredith Young refers to the increased number of deaths resulting from, or attributed to, malignant diseases during recent years. No fewer than 747 deaths were attributed to these causes, as compared with 678 in 1918 and 711 in 1917. The cancer death-rate per 1000 of the population was 0·70 in 1900, 0·77 in 1905, 0·84 in 1910, 1·25 in 1915, and 1·24 in 1919. In connexion with the cancer problem, it has occurred to many that there might be advantage in making the disease notifiable in a number of selected districts with a view to careful inquiry being made by trained observers into the circumstances associated with each case. Valuable information respecting the natural history of the malady would thus be obtained, which, together with laboratory research, might result in elucidation of some of the questions concerning the cause of the disease and the factors which predispose to attack.

Ten cases of small-pox occurred in the urban district of Lower Bebbington during 1919. These were attributed by the district medical officer of health, Dr. J. B. Yeoman, to spread of infection from the Liverpool Port Sanitary Authority's hospital at New Ferry. Dr. Meredith Young, though not a believer in the aerial transmission of small-pox infection, states that there are numerous other ways in which the disease may be carried from a small-pox hospital to adjoining premises, and adds that the outbreak in question is by no means the only one in which small-pox has appeared in the vicinity of the hospital under circumstances which appeared to point to the hospital being the direct or indirect source of infection. The deaths recorded as due to influenza in 1919 numbered 884, or approximately half the number which occurred during 1918. In some areas it was found practicable to enrol a number of women possessing a reasonable amount of skill in home nursing whose services were available, under professional direction, for the nursing of patients during widespread outbreaks of the disease. This system has much to commend it, particularly now when the exigencies of war have produced a large number of educated persons who have gained a fair amount of nursing experience. Work of this nature is suitable for those who have assisted to nurse the sick and wounded under the schemes of the Order of St. John and the British Red Cross Society.

The annual report contains, as usual, a section devoted to the important subject of maternity and child welfare, written by Dr. Jane R. Shaw, the lady assistant medical officer of health. The proportion of trained midwives practising in the county now amounts to 56 per cent., which shows a considerable falling-off of the "bona-fide" midwife. Great difficulty is still experienced in obtaining midwives to fill the places of those who retire, and this will always be the case until both the status and remuneration of the midwife are made commensurate with the responsible nature of the duties which she has to carry out. In certain districts midwives have been appointed each at a salary of £100 per annum, while in a number of other areas the services of nurse midwives have been obtained by arrangement with the County Nursing Association. This plan has been found to work most satisfactorily. The county maternity and child welfare staff comprises a lady assistant medical officer of health and 26 whole-time and one part-time health visitor. With three exceptions each health visitor is responsible for the visiting of children under 5 years of age. She also assists in the work of medical examination of school children, and in the treatment and prevention of tuberculosis, besides attending the maternity and child welfare centre in her particular area. The arrangements made for visiting infants during the period under review were similar to those of previous years. Cases attended by an untrained midwife were visited as soon as possible after the birth, and those attended by a doctor or a trained midwife were visited after the tenth day. The health visitors sent every week to the county medical officer of health a report of the work done during the preceding week, and a report, on special forms, of every baby visited and revisited. These reports are carefully scrutinised by the lady assistant medical officer of health and a duplicate of each form filed for future reference. During the first year of their age the babies are usually visited once a month, but it is found necessary in many cases to visit more frequently. During 1918, with one exception, the number of visits to notified babies under 1 year amounted to an average of ten visits per child, which was regarded as satisfactory. During 1919, however, the average fell to about six visits per child. This was due to the increased amount of tuberculosis and school inspection visiting that the health visitors had to do. Every branch of the health visitor's work is important, and if she is to devote sufficient time to each she should be given a much smaller area than is at present allotted to her. Such an arrangement would, of course, involve a considerable increase in the number of health visitors employed. In November, 1919, an antenatal clinic was opened as an experiment in this branch of the work. A specialist in obstetrics and gynæcology was appointed to attend at its fortnightly sessions. During the six months the clinic has been open 48 patients attended on one or more occasions, being sent by their own doctor or brought by the midwives engaged to attend the confinement. A complete history was taken in each case, the patient's condition being carefully investigated. The urine of every patient was examined, and where circumstances required pelvic measurements were taken. Advice was given regarding appropriate diet, exercise, and the general hygiene of pregnancy. In the event of any special medical or surgical treatment being necessary a letter was sent to the patient's own doctor on the subject.

It is obvious that excellent work is being carried on in Cheshire in connexion with maternity and child welfare, which will doubtless have important influence on the future health of the community.

City of Birmingham.

Dr. John Robertson's annual report for the year 1919 contains as usual much interesting material. He lays special emphasis once more on the importance of housing conditions in relation to health. In his opinion much still remains to be done in Birmingham to improve the health and social conditions of the people, and, in this connexion, the condition that overshadows everything else is the housing question. There are a large number of houses in the city where two or more families are living in the accommodation provided for one family. The shortage of houses is so acute that there does not at present appear to be any prospect of making up the deficiency for many years. If 2000 houses are built per year, it will not do more than meet the ordinary increase in population. Something more, therefore, is needed than 2000 new houses each year. In the meantime the old houses are getting into an increasingly defective condition. In some cases steps have to be taken to prevent parts of old dwellings from collapsing. In the ordinary course these houses would have been demolished at the rate of from 300 to 500 per annum, as they are old and dilapidated and the leases are running out. For the central areas of the city something more than mere house-building is required. It is most important that these districts should be subject to a modified form of town-planning, so that in time many of them, in which the conditions are at present degrading, may be brought to a standard commensurate with the minimum requirements for reasonable healthy existence. The arrears of work on housing are so great that, in Dr. Robertson's opinion, almost everything else in the way of city expenditure should give place to it. Having regard to the fact that Birmingham contains one of the largest industrial populations in the Empire, the health of the city is exceptionally good. The death-rate for 1919 was 13·0 per 1000; the infantile mortality-rate, 84; the phthisis mortality-rate, 1·10; the non-pulmonary tuberculosis-rate, 0·18; while the new cases of enteric fever gave a rate of 0·04 per 1000. Comparison of the health statistics of one community with those of other more or less similar communities is always interesting. For this purpose the general death-rate and infantile mortality-rate respectively of each of the eight largest towns may be given: Glasgow, 16·4 and 114; Birmingham, 13·6 and 88; Liverpool, 16·8 and 107; Manchester, 14·0 and 95; Sheffield, 13·7 and 96; Leeds, 16·0 and 112; Bristol, 13·1 and 82; Edinburgh, 16·8 and 117. It will be noted that the general death-rate and infantile mortality-rate of Birmingham are lower than the corresponding rates in any of the other towns with the exception of Bristol.

On the subject of the treatment and prevention of tuberculosis Dr. Robertson thinks that the persons who hold somewhat gloomy views as to the success of existing methods do not appreciate the following important facts—namely, that tuberculosis is mainly a very chronic disease, and that measures taken to-day will only be apparent in their effects in some years to come. In most areas what has been done is so trivial in amount that it could not be expected to substantially reduce the prevalence of such a disease. "Notification" has brought to light and labelled many persons whose deaths would have been classified under other headings but for notification. Four years of war have profoundly influenced many lives. War conditions put a strain on the soldier and the civilian alike, lowering resistance and making those with any nidus of infection succumb to it. The Birmingham figures were worse during the war years than before, so far as deaths go. Immediately the war terminated they commenced to improve. There are now fewer deaths than before the war and there are far fewer new cases. As regards the result of treatment, there is reason to value what has been accomplished. Treatment is directed to prevent infection spreading, and to the arrest of the disease in the individual. There is no doubt that fewer cases in young adults are now met with. In connexion with the arrest of the disease, the following figures for the first year of complete notification (1913), when a large number of chronic and severe cases came on the register for the first time, show what may be considered as the worst results, but even these are very much better than those reported from towns which have dealt with tuberculosis in a half-hearted way. The total number of cases of pulmonary tuberculosis notified in 1913 was 4146, and the number whose history has been followed up to April, 1920, was 3104. Of these 3104 cases, 1371, or 44 per cent., have died during the past six years; 1540, or 50 per cent., are doing usual full-time work, while 80 are doing part-time work; 89 are not able to do any work at all and 24 have no occupation. There were 935 deaths registered during 1919 as due to cancer. This is equal to 1 in every 13 deaths occurring during the year. Of persons 20 years of age and over the deaths during 1919 represented 1 in every 9 deaths. The total number of deaths attributed to cancer in each year since 1911 were as follows: 1911, 748: 1912, 791: 1913, 893; 1914, 773; 1915, 885; 1916, 897; 1917, 912; 1918, 883; 1919, 935.

The excellent work carried on in Birmingham in connexion with maternity and child welfare still continues and the year 1919 showed a lower infant mortality-rate than any previous year on record—namely, 84 per 1000 births. The rates in previous years were as follows: 1871–75 (old city area), 182; 1876–80, 164; 1881–85, 161; 1886–90, 173; 1891–95, 176; 1896–1900, 199; 1901–05 (extended city), 157; 1906–10, 131; 1911–15, 126; 1916, 104; 1917, 101; 1918, 99; 1919, 84.

City of Glasgow.

This is the first annual report issued by Dr. A. K. Chalmers since the commencement of the war, and it has reference to health conditions in the city during the six years 1914–19. Even a cursory examination of its pages shows the rapid progress that has been made in certain branches of public health work during the period under review. More particularly is this the case in connexion with maternity and child welfare, the treatment of tuberculosis, and the measures adopted for the prevention and treatment of venereal diseases. It is satisfactory to know that, despite the strain on the civil population during the period in question and the pandemic of influenza towards its close, which increased the death-rates of the fourth and first quarters of 1918–19 to quite unusual ranges, the average health of the population was fairly maintained, and the rates on the whole were lower than during any previous period of like duration. How much of this improved health was due to the more orderly lives of the civilian population, to the better feeding of children, and to reduced drunkenness may be matter of opinion and not readily demonstrable, but it was the uniform experience of the visiting nurses and others, whose daily work took them into the houses of the poorest of the population, that food and furnishings and habits were all improved.

The report contains an interesting preliminary statement respecting the results of an inquiry into the causes of stillbirths. It is frequently stated, and commonly accepted, that syphilis is a dominant factor among the causes of fœtal deaths, and the inquiry was instituted with the double purpose of ascertaining how far this is actually the case in children stillborn at full time, and also to learn what gross physical lesions were present in the stillborn children and whether they were of a character which made preventive treatment of the mother reasonably possible. The inquiry was conducted by Dr. R. M. Buchanan, the city bacteriologist, but it was not intended to report until a much larger number of examinations had been made, and the present preliminary statement was made in response to a request for information on the subject by the Scottish Board of Health. In summarising the results so far obtained by Dr. Buchanan, Dr. Chalmers states that as a cause of death at full time syphilis does not appear to be a predominant factor. There is some indication, however, that it is more frequently operative at earlier stages of pregnancy, as illustrated by the relatively large number of fœtuses in which its presence could be demonstrated in miscarriages occurring between the sixth and eighth month of pregnancy.

URBAN VITAL STATISTICS.

(Week ended Jan. 8th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 15·3, 15·1, and 15·6 in the three preceding weeks, fell to 13·9 per 1000. In London, with a population of 4½ million persons, the death-rate was 12·9, or 3·6 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 6·5 in Rotherham, 6·7 in Walthamstow, and 7·4 in Bury to 22·6 in Hastings, 23·2 in Halifax, and 24·5 in Sunderland. The principal epidemic diseases caused 231 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 90 from infantile diarrhœa, 60 from diphtheria, 28 from measles, 26 from whooping-cough, 22 from scarlet fever, and 5 from enteric fever. The mortality from these diseases showed no marked excess in any of the large towns. There were 4608 cases of scarlet fever, 2588 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4817, 2642, and 1 respectively at the end of the previous week. The causes of 38 of the 4964 deaths in the 96 towns were uncertified, and included 4 each in Liverpool and Preston, and 3 in West Hartlepool.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had increased from 13·5 to 18·4 in the five preceding weeks, was again 18·4 per 1000. The 382 deaths in Glasgow corresponded to an annual rate of 18·1 per 1000, and included 11 from whooping-cough, 6 from infantile diarrhœa, 3 from diphtheria, 2 from small-pox, and 1 each from measles and scarlet fever. The 145 deaths in Edinburgh were equal to a rate of 16·9 per 1000, and included 14 from influenza, 2 from measles, and 1 each from scarlet fever, whooping-cough, and infantile diarrhœa.

Irish Towns.—The 139 deaths in Dublin corresponded to an annual rate of 17·1, or 9·8 per 1000 below that recorded in the previous week, and included 3 from infantile diarrhœa, 2 each from enteric fever and diphtheria, and 1 from whooping-cough. The 157 deaths from Belfast were equal to a rate of 19·5 per 1000, and included 6 from infantile diarrhœa, 3 from diphtheria, and 1 from whooping-cough.

The Services.

HYGIENE IN THE ARMY.

THE important part which hygiene plays in maintaining the efficiency of troops is emphasised in an Army Order just issued. Command Schools of Hygiene are to be established at Aldershot (when the transfer of the school at Blackpool is effected); Hertford Barracks, Hertford; Strensall Camp, near York; Dreghorn Camp, near Edinburgh; Hilsea hutments, Portsmouth; and Carrickfergus. These schools are to be permanent centres of instruction for staff and regimental officers and for regimental sanitary personnel; and they will maintain close liaison with neighbouring units in order to facilitate the demonstration of the principles of practical hygiene on model lines. Four classes for officers will be held annually, and the classes for regimental non-commissioned officers and men will extend over a period of three weeks. Classes for personnel of the Royal Air Force will run concurrently with the Army classes, and Territorial Force sanitary companies will be attached to the Command Schools for instruction during their period of training.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Cmdrs. R. C. Munday, T. W. Philip, M. H. Knapp, and J. A. L. Campbell have been placed on the retired list with the rank of Surgeon-Captain.

ARMY MEDICAL SERVICE.

The undermentioned Major-Generals retire on retired pay: L. E. Anderson and G. Cree.

ROYAL ARMY MEDICAL CORPS.

The undermentioned are placed on the half-pay list on account of ill-health: Lieut.-Col. G. J. S. Archer and Major H. S. Dickson.

The undermentioned relinquish the acting rank of Major: Temp. Capt. R. B. Wallace and Capt. and Bt. Major J. D. Bowie.

Capt. W. Walker to be acting Major.

The undermentioned to be temporary Captains: Temp. Lieut. H. J. Brink and E. Tanton (late temporary Captain).

Officers relinquishing their commissions:—Temporary Captains retaining the rank of Captain: G. Fildes, P. A. Dargan and H. J. H. Symons (on appointment to I.M.S.), R. Stephens, P. MacD. Little, and T. Sheehan.

Temp. Lieut. J. S. F. J. Kerr retains the rank of Lieutenant.

TERRITORIAL FORCE.

Capt. R. Phillips to be Major.

Capt. T. M. Jamieson, from 4th Southern General Hospital, to be Captain.

1st London (C. of L.) Sanitary Company: Major L. T. F. Bryett resigns his commission and retains his rank, with permission to wear the prescribed uniform.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of the following officers: Lieut.-Cols. J. L. Macrae, G. T. Birdwood, G. H. Frost, A. Miller, and Col. P. J. Lumsden.

ROYAL AIR FORCE.

Capt. A. E. McCulloch relinquishes his temporary R.A.F. commission.

Obituary.

SAMUEL ARCHIBALD VASEY, F.I.C., F.C.S.,

DIRECTOR OF "THE LANCET" LABORATORY.

THE death of Mr. S. A. Vasey on Jan. 7th, after a brief illness, came as a great shock to his friends.

Born in London on March 9th, 1866, the son of Samuel and Alice Marwood Vasey, he was educated at the Leyton and the City of London Schools, going on then to Charing Cross Hospital Medical School, as it was at that time his intention to become qualified as a practitioner of medicine. Always keenly interested in chemistry and its application to hygiene and industrial research, he took his Fellowship of the Chemical Society in 1883, and almost at once became assistant to Professor C. W. Heaton, who had made a name at Epsom College, and later as lecturer on chemistry at Charing Cross Hospital, by arousing a living interest for the principles of chemistry among his pupils. Professor Heaton, who was public analyst to the parish of St. Martin-in-the-Fields, was at that time supervising the conduct of THE LANCET Laboratory. Vasey became his assistant also in that work, and on his death in 1893 took over the whole responsibility at the early age of 27 years.

S. A. VASEY.

For 28 years Vasey continued to direct the inquiries of all sorts conducted at THE LANCET, and it may well be doubted whether in this time any important work in chemistry or physics, and having a bearing upon the health and happiness of humanity, escaped his notice. Already in his first year of office we find him reporting on an Inquiry into the Character and Quality of the Ice-supply of London, on the Metallic Contamination in the Manufacture of Mineral Water, on a Special Analytical Sanitary Commission on Gaseous Fuel, and on another Commission on Tannin and Theine in China and Indian Teas. This work was a continuation of a scheme laid down by the founder of THE LANCET and carried on with energy by him and by his son, Dr. James Wakley, who succeeded him as Editor. The scheme was to institute inquiries by the paper, to which the title "Lancet Commissions" was given, under which persons with particular knowledge and authority should institute close inquiries into the circumstances where the public health was indifferently safeguarded, and should publish their results, THE LANCET taking the consequences. At the time when the scheme took shape the public was without the numerous forms of protection which have since been furnished by various Acts of Parliament. To assist in the actual inquiries and to conduct any physical and chemical investigations necessitated, a laboratory was founded and a director appointed, whose first inquiry, which was published in January, 1851, proved that most of the coffee on the market, sold under various alluring titles, was grossly adulterated. The excitement was created which Wakley expected, and the method employed in dealing with the analysis of coffee was followed in the analyses of other food and medicinal substances during the next ten years, when the scope of the investigations assumed a different character and while all sorts of foodstuffs came under investigation, such great subjects as the conditions of out-door poor relief, the water-supply of London, and the baking trade were dealt with. In connexion with the last inquiry Mr. Adolphe Smith, later to be associated with Vasey in so much public work, made his first report to THE LANCET.

Thus, when Vasey came to the laboratory the terms of reference were of the widest, and during his tenure investigations have been undertaken of so heterogeneous a character that we can only single out for notice a few of them; and concerning these we may say that, while the wide range proves Vasey's catholic equipment, we are not compelled to praise our friend or the nature of his work, for in scores of text-books his findings have been recorded with approval, and into more than one Act of Parliament his recommendations have found their way practically unchanged. Vasey was the author of a shrewd series of articles on the nature of quack abortifacients and the part author of a useful report upon the standardisation of disinfectants. These things are mentioned to show his skill at the bench. He made a thorough investigation into the physics of gas lighting and into the whole subject of heating by means of gas, and in the course of the latter work he supplied manufacturers of gas stoves with much information which they required for regulating the mechanism, and for obtaining economical results. Later, Vasey brought his intimate knowledge of air impurity to bear upon the whole subject of coal-smoke abatement. He was a strong supporter of the Coal-Smoke Abatement Society, and one of the first stations fitted up by the Meteorological Office, when the subject was put on a sound scientific basis, was in THE LANCET laboratory. He was also the author of three exhaustive inquiries into the two forms of alcohol sanctioned by the British Pharmacopœia—brandy and sherry—and into claret, the most frequent wine of ordinary drinking. His chemical résumés of these subjects constituted only a part of the interest of the articles. He took full opportunity during his investigations at the vineyards, to acquire information about soil, weather, and traditional routine, giving a broad character to the history of the three fluids. Others of his inquiries conducted far afield were those into the chemistry and natural history of continental waters such as Apollinaris and Hunyadi Janos and to the stock-breeding areas belonging to the Liebig Company. The medical profession were wisely informed by him, also, on such various topics of public interest as the nicotine contents of tobacco, with reference to pipe-, cigar-, and cigarette-smoking; the food value of oysters and the risks in their breeding and supply; and the measure of danger incurred by using certain flannelettes. In stopping at this point in our enumeration we do so because it is not easy to select, for any reasonable summary, the particular inquiries which have been either the most useful publicly, or displayed his skill in the most marked manner. The results of 28 years of application, knowledge, and intuition are accessible in our files.

Vasey's application of science to the things of daily life was not conscious or intentional, it had become part of his mental make-up. This was notably the case in regard to food. A luncheon to him was not (say) sausage and potatoes, it was 1250 large calories with too low a protein factor and a probable deficiency in fat-soluble A. A walk along the Strand or a fog-delayed journey from Cannon-street to Charing Cross afforded him material for interesting and informed comment. His mind was arranged on the pattern of a Royal Institution Christmas lecture, to be addressed to grown-ups instead of to children. Atoms and ions and sols became simple when he wrote about them because they were not in a separate compartment of his thoughts labelled "science," but were jostling in familiar company with food and drink and clothes and the raw materials of industry. Doubtless the fact that he was largely self-taught, and had taken little pains to spread out his mental equipment before the cold eye of the examiner had much to do with this freshness and originality.

Vasey was a man of many accomplishments and interests outside his purely professional work, and the first of these was music, which was a never-ending source of pleasure to him. He had that gift which but few possess in like measure, a talent for improvisation; this showed itself, not as an aimless wandering from chord to chord, but as a well-ordered and formal treatment of a theme. His knowledge of harmony seemed intuitive, although modernists would have thought it dull. His favourite composer was Handel, and after him Bach and the dignified and restrained followers of the Church school of Palestrina, Gibbons, and the Elizabethan madrigalists. He took delight in plain-song, and his taste in hymn tunes would have satisfied Sir Hugh Allen, for he could not stand the washy part-song brand of tune. He could talk well and learnedly without being arid on the by-ways of chemistry and physics, and was a charming and sympathetic host. Until a form of writer's cramp spoilt his grip he was a keen golfer, and he was for five or six consecutive years captain of the Sundridge Park Golf Club, to the great and publicly expressed appreciation of the members.

Our readers will sympathise with us in the loss which we have sustained by this untimely death. We have endeavoured to show the wide range of his equipment and the practical nature of his services to the public for a long and uninterrupted period. He died in harness. Those who are responsible for the conduct of this journal will have an abiding recollection of many years of intimate association. We drew on his knowledge unceasingly, and from his fertile imagination and shrewd judgment we received many suggestions, valuable to ourselves, and having no close relation to his immediate sphere of activity. He has left in his laboratory an orderly collection of his voluminous contributions to our columns. This is particularly fortunate because Vasey was a living dictionary of public health, where public health was in contact with his work, and for many years his voice will be with us full of wise counsel.

He married in 1900 Gertrude, youngest daughter of John James Griffiths, J.P., of Highbury, and to his wife, who survives him, deep sympathy will go out.

The calamity was unexpected, though the end cannot be termed sudden. On Dec. 2nd, after a long day at his work, he was taken ill with acute bronchitis, which became broncho-pneumonia. There were periods of improvement, but signs of cerebral and meningeal involvement developed towards the end—and he died on Friday, Jan. 7th, at his house, "Beechcroft," Bromley, Kent, in the fifty-fifth year of his age. The funeral took place on Tuesday last at Plaistow Cemetery in the presence of a large attendance.

ROBERT JARED BLISS HOWARD, M.D., C.M. McGILL, F.R.C.S. ENG., L.R.C.P. LOND.

Dr. Robert Jared Bliss Howard, who died on Jan. 9th, was the only son of the late Dr. Robert Palmer Howard, dean of the Faculty of Medicine and professor of medicine in the University of McGill. Born in 1859, he was educated at the High School, Montreal, and afterwards at the University of McGill, where he graduated B.A. with first-class honours in Natural Science in 1879, proceeding to the M.D., C.M. degrees in 1882, again with honours, and taking the gold medal. In the same year he obtained the M.R.C.S. Eng. and the L.R.C.P. Lond., and went with the late Sir William Osler, who had been a student under his father, to Berlin, and afterwards visited clinics at Vienna and Leipzig. Later he assisted his father in practice at Montreal, and became demonstrator of anatomy and surgery at McGill University, pathologist and assistant surgeon to the Montreal General Hospital, and surgeon to the Montreal Dispensary. He became a Fellow of the Royal College of Surgeons of England in 1884, being one of the first graduates of a colonial university to take this diploma. During the South African War he worked at the Guards' Hospital, Rochester-row, and during the recent war he organised and supervised the Mount Royal Home for Officers at Bath, and also worked at the 3rd London General Hospital at Wandsworth. For his services he received special mention and was awarded the O.B.E.

Dr. Howard married in February, 1888, Margaret Charlotte, daughter of Donald Alexander Smith, afterwards first Baron Strathcona and Mount Royal, by whom he had three sons and two daughters. His second son was killed in action in May, 1915. The elder will succeed to his mother's barony.

EDWARD COLLINS BOUSFIELD, M.R.C.S. ENG., L.R.C.P. LOND., D.P.H.

Mr. Edward Collins Bousfield died at his residence, De Crespigny-park, London, S.E., on Jan. 7th, aged 65. He received his medical education at St. Bartholomew's Hospital, where he was physiological prosector from 1876 to 1878, in which latter year he qualified with the Membership of the Royal College of Surgeons of England. The following year he obtained the Licentiateship of the Royal College of Physicians of London, and devoted himself almost exclusively to the work of bacteriological research. The experience which he gained as pathologist to the Wellcome Physiological Research Laboratories and at the Medical Graduates' College and Polyclinic led to his later appointments as bacteriologist to the metropolitan boroughs of Camberwell and Hackney and as the director of the Camberwell Research Laboratories. He was also deputy medical officer of health for Camberwell and Metropolitan Asylums Board Ministry of Health representative.

As a microscopist he contributed several useful papers on various subjects to scientific societies, was the author of a work on microphotography, and edited the late Rev. J. G. Woods's "Common Objects of the Microscope." To our own columns he contributed an interesting article on "An Attempt to Rehabilitate the Permanganates" (vide THE LANCET, Oct. 10th, 1908, p. 1078), and as recently as August, 1919, he described as a unique disease a condition to which he gave the name of cryptopodia.

MANCHESTER RADIUM INSTITUTE.—Sir William Milligan, honorary secretary and treasurer of the Institute, has announced that out of £30,000 asked for barely £9000 have been subscribed by the public. Owing to the Institute's lack of radium it is impossible to give the necessary treatment with full dosage to the ever-increasing number of patients applying for relief. The new hospital, with its in- and out-patient departments—the first fully equipped radium hospital in the United Kingdom—will afford opportunities for much valuable work being done, not only from the therapeutic but also from the research point of view.

TURNER MEMORIAL HOSPITAL, KEITH: DISPOSAL OF A TRUST FUND.—The Second Division of the Court of Session have granted the petition of the trustees of the late William Gordon, who died in 1906. In 1905 by a codicil of his will he provided that the farm and lands of Rosehall should be held by his trustees as a permanent and inalienable endowment to the Turner Memorial Hospital, Keith. By a later codicil he gave a sum of £1000 as a further endowment to the hospital. From July, 1906, to December, 1918, the average surplus revenue paid in respect of the Rosehall subjects to the directors of the hospital was £28 4*s.* per annum. For the year 1919 there was a debit balance of £5 14*s.* due to the cost of repairs and increased rates. The trustees came to the conclusion that it would be of advantage if Rosehall could be sold and the proceeds invested in trust securities, in view of prospective heavy expenditure on the property and increased rates. The petitioners accordingly advertised Rosehall for sale, and got an offer of £1350. The present tenant offered £1450, which the petitioners now asked the Court to authorise them to accept. They submitted that this sum invested in Government funds would produce a net revenue for the hospital of £70.

OSTEITIS DEFORMANS?

To the Editor of THE LANCET.

SIR,—I read with great interest the note on osteitis deformans, contributed by my friends Mr. Frank Romer and Sir W. Arbuthnot Lane. Whether the cases described are identical with those originally observed by Sir James Paget it is not easy to decide. I have seen a number of cases where for years the affection has been localised to one or both tibiæ, but I have also seen a case where the disease became distributed after having been confined to one tibia for over ten years. In this case the second tibia, the clavicle, and the skull were ultimately attacked. I have operated on many cases generally with marked relief; on some I have had to operate a second time. Usually a linear incision along the length of the thickened bone right into the medulla suffices. In cases of marked bowing accompanied by pain both in the bone and knee-joint I have removed a wedge from the tibia and straightened the limb. The fracture heals readily. About 15 years ago I removed a wedge from a very crooked and painful tibia which presented symptoms very similar to those described by Mr. Romer's first patient. The microscopic appearances of the bone removed were described as those of chronic osteitis. I saw him five years later, and his leg had remained quite straight and his pain was trivial. Some of these localised cases give no history of accident.

I am, Sir, yours faithfully,

Liverpool, Jan. 8th, 1921. ROBERT JONES.

THE FUTURE OF THE POOR-LAW INFIRMARIES.

To the Editor of THE LANCET.

SIR,—I should regret if any observations of mine in opening the discussion at the Harveian Society on the future of the Poor-law infirmaries have brought annoyance to anyone professionally connected with these institutions. At St. Mary's we are not in the least likely to underrate the efficiency of the infirmary personnel. On the contrary, we are agreed that the successful development of the affiliation scheme between St. Mary's and Paddington Infirmary during the past year is due in great measure to the medical superintendent and his resident staff. In particular we have been impressed by the possibilities of such a post as medical superintendent of an infirmary, to which there is no exact analogy in a general hospital, when, as in the case in point, there is found a happy union of clinical acumen and administrative capacity.

Statements, when they are lifted not bodily but piece-meal from their context, can proverbially be made to mean anything. Those of which Dr. J. C. Muir complains in your issue of Jan. 1st were so qualified in the text that it was plain that they implied no personal reflections whatsoever. I had hoped that it was sufficiently clear in my paper that these shortcomings are, in my opinion, made inevitable "by the very nature of the limited personnel and the financial arrangements." The medical superintendent, with the help of two or three residents, and such assistance as may be forthcoming from weekly visits of one or two consultants, has to compete with a mass of clinical material which would elsewhere engage the whole energies of 12 to 20 residents, aided by clerks and dressers, and of a consultant staff 20 to 30 in number, to say nothing of registrars and accessory services. If they were archangels it could not be done. A few of the infirmaries, as we know, are exceptionally equipped, and the arrangements between St. Mary's and Paddington Infirmary are on more ambitious lines, but it was of the majority that I spoke. Of these I held, and still hold, that much remains to be done to convert them into modern hospitals. The statements that I have made in support of that contention are, according to Dr. Muir, misstatements. We must leave it at that. It is of more moment that we are agreed as to the necessity for change.

When I was asked to open this discussion I ventured to suggest that a medical superintendent should be invited to take part in the debate, and that suggestion I repeated when the question of an adjournment came up. I think we can learn a great deal from criticism—from mutual criticism—if of a constructive nature, and I was under the impression that I had made it clear that many of us who are associated with the voluntary system are very conscious that it is far from perfect.

I write because I am in full accord with Dr. Muir that the spirit in which we approach the linking-up of voluntary hospitals and infirmaries is of the very first importance. Whether his letter or my paper more conduces to that end must be left to others.

I am, Sir, yours faithfully,

South Audley-street, W. Jan. 11th, 1921. C. M. WILSON.

OCCUPATIONAL HYGIENE AND THE SCHOOL MEDICAL SERVICE.

To the Editor of THE LANCET.

SIR,—I was very much interested in reading your leading article of Jan. 1st, which ably illustrates the highly unsatisfactory position and prospects of the junior whole-time school medical officer. Undoubtedly his lot is not a happy one, and certainly commands sympathetic consideration. The work is departmental, entirely executive, running in a monotonous groove, and the greater the number taking it up the less chance there is for the individual to get out of it. I agree that the situation is serious and should be ameliorated. At the same time I am somewhat surprised at the remedy suggested by the writer of the article, and equally so at his apparent faith in the infallibility of his cure. I am not unacquainted with factory medical work or public health administrative methods, and therefore do not hesitate to assure you that absorption of the certifying surgeon would simply mean a further increase of junior whole-time officers without any real bettering of unsatisfactory conditions. The only one to enjoy variety would be the administrative officer, as the executive work of factory medical service, at any rate in industrial areas, would certainly have to be undertaken by a separate department. Apart, however, from its doubtful efficacy, is it wise or proper to advocate the advancement of one section of the profession entirely at the expense of another section?

The attempt at justification has no stronger foundation than conjecture and the average certifying surgeon would probably find little difficulty in proving this (to his own satisfaction at least) to be as fallacious as the recommended cure. At any rate, the pushing of a theory of this kind means the promotion of a serious dispute within the profession. This would probably end unsatisfactorily for both parties, and would certainly give a good fillip to a third method of dealing with industrial medical problems which has already many supporters outside the profession. At a time when our medico-political leaders are advocating unity of the profession, and are impressing upon us the necessity of showing ourselves capable of working out our own future, is it not best to leave contentious matter of this nature severely alone? My own view is that it would be much more to the advantage of both these sections of the profession, as well as of the community at large, if they worked together to obtain a useful coördination of their separate functions and a general improvement of the disadvantageous conditions under which both are employed. To my mind the appointment of whole-time junior officers for executive work has been overdone, and I would venture the opinion that the only satisfactory way to get out of the blind alley is by a more general establishment of part-time service.

I am, Sir, yours faithfully,

W. F. DEARDEN,
Hon. Secretary, Association of Certifying Factory Surgeons.

168, Trafford-road, Manchester. Jan. 7th, 1921.

TABES:

ITS EARLY RECOGNITION AND TREATMENT.

To the Editor of THE LANCET.

SIR,—Dr. E. F. Buzzard, in a valuable article with this title, published in THE LANCET of Jan. 8th, states:—

> "We are all asked 'How long must I go on with treatment before I am cured?' For many years my answer has invariably been, '*For the rest of your life.*' *I am never consulted about a primary chancre, but if I were my advice would be the same.*"

The statement is a pessimism not calculated to encourage prompt diagnosis and zealous early treatment, *and should not pass unchallenged.* On the contrary, I venture the dogmatic assertion that if a patient first comes under treatment while the blood is still negative (it is here the Wassermann test is of prime value) and receives the usual course of 2·6 g. of "606" and 8 gr. of mercury, the disease will be "knocked out." I shall be contradicted, but if I am not telling the whole truth, it is near enough for propaganda purposes. Personally I know of no exception and in the army I discharged such cases with much assurance. Unfortunately all trace of these men is lost, but surely by now there is sufficient material available to settle this important point and to define the rare exceptions which others may have to relate, where a full course has been given early and yet failed to eradicate the disease. The pathology of both gonorrhœa and syphilis teaches us that nothing can or ever will compensate for damning delay in diagnosis, but with early diagnosis one may be altogether optimistic concerning the ultimate result.

I am, Sir, yours faithfully,

Leicester, Jan. 9th, 1921. JOHN DONALD.

ORAL SEPSIS,

WITH SPECIAL REFERENCE TO CHRONIC DENTAL APICAL INFECTION.

To the Editor of THE LANCET.

SIR,—I find myself in agreement with much that Dr. Stanley Colyer says in his letter in your issue of Jan. 8th. It was not my object, however, to give an account of the history or literature dealing with oral sepsis or dental radiography. Had this been so I should have quoted the words of Rush, an American doctor, who, in 1801, only a quarter of a century after the Declaration of Independence, wrote: "I have been made happy by *discovering that I have only added to the* observations of other physicians in pointing out a connection between the extraction of decayed and diseased teeth and the cure of general diseases." Dr. Colyer will have noted that in my paper I referred to Dr. William Hunter as the pioneer in this field of research in England. Dr. Colyer appears to miss the purpose for which the paper was written, which was, as I stated, "to draw particular attention to one special part of the problem, that of chronic focal apical infection." For many years most of us have been preaching "the gospel of the clean mouth," but what I wished to emphasise was that the diagnosis of a clean mouth is impossible either by the doctor or the dentist without the aid of the radiographer. I submit that this fact is only beginning to be generally recognised in this country, and that a dental *radiographic* investigation does not form a part of the routine examination of the patient here as it does now in America. Further, the utilisation of radiography by the dentist for the many purposes for which it is helpful is in England the exception, in America the rule.

My experience is "small"—not with reference to oral sepsis in general, but merely in those cases with apparently clean and healthy mouths, revealing after radiographic and bacteriological investigation active foci of infection in the alveolus. Both doctors and dentists have been slow in grasping the importance of chronic dental apical infection and have not availed themselves *of this method of diagnosis to the extent* that they should. In my paper I asked the question, "Is simple extraction adequate?" I am sure your readers, like myself, would welcome Dr. Colyer's opinion on this point.—I am, Sir, yours faithfully,

Harrogate, Jan. 8th, 1921. W. BERTRAM WATSON.

DILUTE SULPHURIC ACID IN FURUNCULOSIS.

To the Editor of THE LANCET.

SIR,—I have read with much interest the "Dissertation upon Carbuncles" by Dr. Sidney Phillips in your issue of Jan. 8th, and agree with much that is contained therein; but when I read that among other internal remedies for this complaint he has found "dilute sulphuric acid" of *no good to him* I can only suppose that either he has not given it a sufficient trial, or that he has not used *dilute sulphuric acid* of the right strength. The proper strength is 10 per cent. of the strong acid, and the dose is 25 to 30 minims of this mixed with 2 ounces of water every four hours. I have now been in practice over 50 years, and have used this remedy with 100 per cent. successes for the last 40 years. If Dr. Phillips cares to know what this remedy can do I would refer him to a communication to THE LANCET of March 15th, 1913, also to the *British Medical Journal* of August 15th, 1908. Letters received from all parts of this country, and also reports from India, confirm my statements regarding this treatment. Lastly, the ordinary B.P. acid sulph. dil. is too weak to be of any use, unless given in *40 minim* doses.

I am, Sir, yours faithfully,

J. REYNOLDS, M.D. Brux., &c.

Brixton, S.W., Jan. 10th, 1921.

THE CULTURAL DIAGNOSIS OF ENTERIC IN INOCULATED INDIVIDUALS.

To the Editor of THE LANCET.

SIR,—Several recent numbers of THE LANCET have contained references to my article of Oct. 30th, 1920, on the Myth of "Atypical" Enteric Fever. It would be impossible to deal adequately with all of these in the form of a letter, and there is only one to which I wish to reply now. Dr. J. C. G. Ledingham, in THE LANCET of Jan. 8th, very justly questions my statement that "the difficulty of recovering enteric bacilli from the blood of inoculated soldiers is well known, even in the early stages of illnesses which clinically resemble enteric." This statement (especially having regard to the context) conveys the impression that I believe that in inoculated subjects enteric fever may exist without bacillæmia, or with a bacillæmia reduced in degree or duration or both, and Dr. Ledingham says that he is not aware of any published data in support of this view. Neither am I, and I thank Dr. Ledingham for drawing attention to the point. It is another of the myths arising out of a desire of some individuals to prove that agglutination provides the most reliable means of diagnosing enteric amongst inoculated soldiers. Dr. Ledingham's figures go far to dispel it.

It is a matter of great satisfaction to me to find that so distinguished an authority should be in sympathy with the substance of my argument. The question is, as Dr. Ledingham remarks, of high theoretical and practical importance. If the myth of "atypical" enteric fever prevails anti-enteric inoculation is not an unmixed blessing. Only when the myth is finally exploded and the dust has blown away can we get a clear conception of what a wonderful scientific achievement was the protection of the British armies from enteric. I am, Sir, yours faithfully,

Jan. 8th, 1921. R. P. GARROW.

RELIEF ON INCOME-TAX IN RESPECT OF SERVICE INCOMES.

To the Editor of THE LANCET.

SIR,—Towards the end of 1919 or early in 1920 the Board of Inland Revenue issued a Memorandum to the effect that civil practitioners doing work in military hospitals should be granted the same relief on their service incomes as army medical officers had received—this concession to be retrospective as far as the year 1916–17. To those whom it concerned this appeared to be a plain act of justice and it was welcomed accordingly. The question then arose, How would the

Memorandum be carried into effect? To many of us the answer seemed simple and to be the necessary consequence of the following considerations. The civil practitioner was to receive the same treatment as the army medical officer; the latter had already received a definite and easily calculated financial relief on his service income; this same relief, now to become available for the civil practitioner, was as readily calculable—then why not regard the problem as a case of excess payment of income-tax and refund the excess? The issue of the Memorandum, it must be urged, was tantamount to an admission that from the year 1916-17 the service income of the civil practitioner had been overtaxed.

On approaching the income-tax authorities on this subject we learned, to our surprise, that the matter could not be dealt with in this plain and direct manner, for the reason that, whereas the army medical officer was assessed year by year (at the special rates) on the actual amount of remuneration for the year of assessment, in the case of the civil practitioner who had included his Service income in the total income from all sources (as he was bound to do), the Service income had been subjected to the "three years' average method of calculation," and that this made all the difference. Following upon this pronouncement, and having submitted the figures for the Service incomes of the years in question, we next received a document which, as it stands, is literally a cloud of figures as appalling and confusing as a November fog. Speaking personally, I do not feel that I have the acumen, even if I had the patience and the necessary time, to subject these ranks of figures to a critical examination, and I think it likely that others will feel with me in this matter. What is to be done? For to accept results without being able to follow the steps of the argument commends itself as little, as to agree to the postponement of the full settlement of the claim for relief until the year 1922-23—i.e., seven years after the relief first came into operation; yet this is what is asked of us.

In these circumstances I propose that we examine, not the figures themselves, but the premisses on which they are based, for if it should appear that these premisses contain a fallacy the whole calculation will of necessity be fallacious. In like manner it is proposed to examine the results of the calculation, for if among these there should be found any one to which the *reductio ad absurdum* argument would be applicable, again the calculation would be invalidated. Now at the very outset the authorities contend that, as a result of the three years' average system of assessment, the amount received by the State in any given year (for income-tax purposes) is one-third of that year's income and no more, and that in consequence two more years must elapse, in order that this particular income may figure twice again in the averaging, before the State will have had the use of the whole sum. This contention is, in my opinion, a complete fallacy, for the three years' average pools the incomes of three whole years and three whole years divided by three yield one whole year's income, not one-third of a year's income. And even if we accept the ingenious way of putting it, adopted by the income-tax authorities—viz., that the figure obtained by the averaging consists of one-third of the given year and one-third each of the two preceding years (which is quite true)—we must point out that the year which *pays* for the sum of these three-thirds is the given year, and three-thirds make one whole. Therefore in any given year the State receives a whole year's income, averaged on three years. Indeed, if the year in question happens to be a lean one as compared with the two preceding years, then the taxpayer, so far from paying on one-third of his income, will pay on more than his whole year's income. The accompanying figures will show this: (1) £600, (2) £500, (3) £400 = £500 average for the three years—i.e., for year, No. 3, £100 in excess of the actual income. Of course, if the third year is a fat year the effect will be reversed. On reflection it must be apparent that the method of averaging does no more than distribute inequalities, an obvious convenience for Budget purposes. If the above reasoning be sound, the calculation is based upon a fallacy and its outcome must be fallacious, including the contention that the tax-payer must wait three years for the settlement of his claim.

Lastly, to examine one other of the actual results of the calculation. I find that for the year 1919-20 (in my own case) it is stated there is due to me in relief for the whole period since 1916-17—i.e., for four years—the sum of £20 18*s.* 6*d.*, but that, per contra, I am in debt to the Revenue to the extent of £89 8*s.* 5*d.*, leaving a balance against me of £68 9*s.* 11*d.* It is true that subsequent years are to make good and that by 1922-23 there is to be an effective ultimate relief of £97 2*s.* 1*d.*, though as far as I can gather it will not materialise in the form of a cheque; that, however, is not the point on which I would lay stress, but this—that in the year 1919-20, having paid in full all my income-tax demands, without any deduction whatsoever on account of my included Service incomes, this calculation finds me in debt to the Revenue to the amount of £68 9*s.* 11*d.*, and this is the result of the granting of a relief! Is not this a reductio ad absurdissimum?

The Trojans were bidden to fear the Greeks "et dona ferentes"; is this to become our attitude of mind towards the income-tax authorities?

I am, Sir, yours faithfully,
HARRINGTON SAINSBURY.
Wimpole-street, W., Jan. 10th, 1921.

SCALDED MILK.

To the Editor of THE LANCET.

SIR,—As there seems to be some confusion as to the wisdom of heating milk for infant feeding by boiling, pasteurising, so-called sterilising, or scalding, I venture to suggest, as the result of the following experiments, that scalding the milk is quite sufficient for all ordinary purposes. One of the principal objects in heating milk is the destruction of tubercle bacilli, and this is effectually accomplished in pasteurising, boiling, or "sterilising," but if the milk is allowed to remain at 100° C. for a considerable period, the activity of the antiscorbutic accessory factor is also all but destroyed. The question therefore to which an answer was required resolved itself into the following: "Is there a period in the heating of milk at which the destruction of tubercle bacilli is assured without serious interference with the activity of the antiscorbutic vitamine?"

To settle this question I was fortunate in seeing at the Lister Institute a monkey in an advanced stage of artificially induced scurvy. So bad was the animal that Miss Harriette Chick had decided to give it antiscorbutic treatment to save its life. She kindly agreed to try the effect of scalded milk. The method of scalding was as follows. The milk was warmed in the gas flame, without stirring, till it frothed up, when it was at once removed and allowed to cool. The milk took 5 minutes to heat and 20 to cool. It was at a temperature of 90° to 100° C. for about 1½ minutes. The monkey was allowed daily 200 c.cm. of this scalded milk and in a short time completely recovered.[1] Scalded milk did not, therefore, destroy the activity of the antiscorbutic vitamine.

The next point was to discover whether scalding was sufficient to destroy the tubercle bacilli. I therefore asked Dr. F. H. Teale's assistance, and he very kindly fell in with my wish. He inoculated milk with an active strain of tubercle bacillus, scalded it as above, and injected three guinea-pigs. In due time the animals were destroyed and were found to be quite free of infection of tubercle.

These simple experiments prove two points: (1) scalded milk retains at least a considerable portion of its vitamine activity; and (2) tubercle bacilli are destroyed by such scalding.

I am, Sir, yours faithfully,
E. A. BARTON,
Medical Officer to Infant Welfare Department,
Jan. 12th, 1921. University College Hospital.

---

[1] Biochemical Journal, vol. iii., p. 317.

Col. Sir W. R. Smith, V.D., T.D., and Dr. G. S. Broc M.B.E., have received from the King of Italy the decoratic of the Cross of Commander of the Order of the Crown of Ital

Medical News.

Society of Apothecaries of London.—At recent examinations the following candidates passed in the subjects indicated:—

Surgery.—S. Davies (Sects. I. and II.), Univ. Coll. Hosp.; R. F. Divecka (Sect. II.), London Hosp.; W. Kilroe (Sect. I.) and M. Melglave (Sects. I. and II.), King's Coll. Hosp.; and J. B. Williamson (Sect. II.), Cambridge and Middlesex Hosp.

Medicine.—S. Davies (Sects. I. and II.), Univ. Coll. Hosp.; L. Dinerstein (Sects. I. and II.), Manchester; C. T. Gasking (Sects. I. and II.), Liverpool and Sheffield; H. D. L. Jones (Sect. I.) and R. J. Little (Sects. I. and II.), St. Mary's Hosp.; E. R. D. Nagel (Sects. I. and II.), St. Thomas's Hosp.; W. R. Ranson (Sects. I. and II.), Middlesex Hosp.; and C. Verheyden (Sect. I.), Utrecht and Univ. Coll. Hosp.

Forensic Medicine.—S. Davies, Univ. Coll. Hosp.; R. J. Little, St. Mary's Hosp.; S. E. J. Miedema, Amsterdam; W. R. Ranson, Middlesex Hosp.; B. W. Rotley, St. Mary's Hosp.; C. Verheyden, Utrecht and Univ. Coll. Hosp.; and J. B. Williamson, Cambridge and Middlesex Hosp.

Midwifery.—J. H. Cooper, Glasgow; S. Davies, Univ. Coll. Hosp.; S. E. J. Miedema, Amsterdam; and M. Tcherny, Zurich.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: S. Davies, R. F. Divecka, R. J. Little, E. R. D. Nagel, and W. R. Ranson.

London School of Tropical Medicine.—The following candidates passed the examination held at the termination of the sixty-fourth session (October-December, 1920):—

*P. A. Buxton (Duncan medal), *H. B. Parker, *H. G. Wiltshire, *L. C. D. Hermitte, *W. B. Cullen, *C. Heppenstall, *R. H. Luscombe, *R. E. Flowerdew, S. C. Bose, E. R. Kellersberger, G. V. Allen, A. A. Denham, H. S. Haji, A. S. Paranjpe, A. Das Gupta, C. J. Caddick, Z. Khaled, P. T. Liang, A. H. Patel, W. R. Taylor, F. Maya Das, S. Somasundram, W. E. de Silva, F. V. Jacques, Miss E. B. Salter, A. M. Kirdany, A. W. Hocker, Miss E. Lombard, A. K. Moilliet, Miss M. Gore, A. R. Mehta, O. van Stems, Miss A. Gore, J. M. McCleery, Miss D. G. D'Abreu, A. F. Abbassi, E. S. Palmer, K. Ponniah, R. Parmanand, A. S. Westmorland, E. T. Saravanamuttu.

* With distinction.

University of London.—*University College:* Courses on the History of Science this term include an introductory course of lectures, continued from last term, on the General History and Development of Science, by Mr. A. Wolf, on Wednesdays at 3 P.M. A course of six lectures, continued from last term, on the History of the Biological and Medical Sciences from Early Times to the Eighteenth Century, by Dr. Charles Singer, on Tuesdays at 5.15 P.M., beginning Jan. 18th, and three lectures on the Development of Medicine in Modern Times, also by Dr. Singer, on Mondays at 5.15 P.M., beginning on March 7th. Fees, for one course, £1 11s. 6d.; for two courses, £2 2s.

King's College Psychological Department.—On Jan. 19th, at 5.30 P.M., Dr. William Brown will begin a course of weekly lectures and demonstrations, extending over two terms, on Experimental Psychology, for medical men preparing for the Diploma in Psychological Medicine. The class will be limited to 10 members, and intending applicants should write to the Secretary, King's College, Strand, W.C. 2, for particulars.

London Dermatological Society.—A meeting will be held at 4.30 P.M. on Tuesday, Jan. 18th, at St. John's Hospital, 49, Leicester-square, W.C. Clinical cases will be shown by Drs. J. L. Bunch, W. K. Sibley, D. Vinrace, W. Griffith, S. R. Kapoor, E. J. D. Mitchell, Eva White, and J. Forbes.

Royal Chest Hospital: Proposed Amalgamation.—A special meeting of the governors of this hospital will be held at the Mansion House on Jan. 17th, at 3 P.M., to consider and, if thought fit, to pass the following resolution:—

> That this meeting of the governors of the Royal Chest Hospital, having considered the guiding features of the scheme laid before them for the amalgamation of the Royal Chest Hospital, City-road, with the Great Northern Central Hospital, and being of opinion that it carries out in effect the intentions of the subscribers and donors of this charity, so far as it is possible in a scheme of this nature, hereby approve the same, and sanction the carrying into effect of the details of the scheme as approved by the council of the Royal Chest Hospital.

Early in 1920 the council of the Royal Chest Hospital came to the conclusion that the financial position of the hospital was such that they could not continue to maintain the hospital for more than a short time, and the Great Northern Central Hospital authorities, having been approached by the council, submitted in March, 1920, a list of the conditions under which they would be ready to continue unimpaired the work of the Royal Chest Hospital. These conditions are now being recommended to the governors of the latter hospital for acceptance.

Royal Institution.—On Thursday, Jan. 20th, at 3 P.M., Dr. Arthur Harden will deliver the first of two lectures on Vitamines.

Post-graduate Course on Infant and Child Welfare.—A course of 12 practical demonstrations on the Management and Feeding of Infants and Young Children will be given by Dr. Eric Pritchard to qualified practitioners, commencing on Jan. 18th. The demonstrations will be given on Tuesdays and Thursdays at St. Marylebone General Dispensary, 77, Welbeck-street, Cavendish-square, London, W., from whose secretary further information and tickets for the course, £2 2s., can be obtained.

National Hospital for Diseases of the Heart: Post-graduate Course, 1921.—A special course of ten lectures, to be held on Mondays at 5.30 P.M., will begin on Jan. 17th, when Dr. B. T. Parsons-Smith will lecture on Mitral Stenosis. The clinical practice of the hospital, both in the out-patient department and in the wards, is open to members of the post-graduate course, for which a fee of £2 2s. per month, or £5 5s. for three months, is charged. Subsequent lectures will be announced in the medical diary of The Lancet. All inquiries should be addressed to the Dean, Dr. P. Hamill.

King Edward's Hospital Fund for London.—A meeting of the General Council of King Edward's Hospital Fund for London was held on Jan. 10th, at the offices of the Fund, 7, Walbrook, London, E.C., with Lord Stuart of Wortley in the chair. The order, signed by His Royal Highness the Prince of Wales, president of the Fund, appointing members of the General Council, members of committees, and officers, for the year 1921, was read. Resolutions providing for the work of the Fund for 1921, which were approved at the meeting or the President and General Council held at St. James's Palace on Dec. 4th, 1920, were formally adopted.

Honour to a Medical Man.—Mr. D. M. Greig, who has been appointed curator of the Museum of the Royal College of Surgeons in Edinburgh, was on Dec. 31st, 1920, presented with the freedom of the city of Dundee. Mr. Greig, one of the best-known surgeons in Scotland, has been in practice in Dundee for 30 years, and was senior surgeon to the Royal Infirmary there.

At the "Aal' 'Eel" gathering of members of the Aberdeen Buchan Association a collection was taken on behalf of Sir James Taggart's building fund for the Sick Children's Hospital, and amounted to £12 2s. 9d. As the result of a concert in aid of the funds for the same scheme a sum of £63 has been handed to Sir James Taggart.

Oldmill Hospital as a Curative Centre.—At a meeting of the Aberdeen Parish Council held on Jan. 6th a letter was read from the Works Department of the Ministry of Pensions confirming the proposed agreement for the Ministry to take over a part of Oldmill Hospital (late 1st Scottish General Territorial Hospital) as a curative centre for disabled ex-Service men.

Manchester Coroner's Report.—The Manchester coroner in his annual report comments on the increasing number of street accidents, and states that during the year 689 inquests were held—slightly in excess of the number in 1919, but 353 fewer than in 1914. 111 inquiries were held last year into the deaths of children under the age of 12 months; of these, 30 were suffocated while in bed with the parents. Of the total inquests held, a third were on children under 16 years of age.

Manchester Royal Infirmary.—The post-graduate lectures and demonstrations on medical, surgical, and special subjects, given by the honorary staff, have been resumed and will be held each week on Tuesdays, at 4.30 P.M. throughout the session. The lectures are free, and a notice of each lecture will be inserted in our diary of the preceding week. The next one will be held on Jan. 18th, by Dr. E. S. Reynolds, on Aphasia.

Manchester Hospitals.—The Manchester Children's Hospital has received from the National Relief Fund a gift of £20,000, a sum which will enable the hospital to pay off an accumulated debt to the bank, but leaves it burdened with making good the annual deficiency on income of many thousand pounds—during the year 1919 the deficit on income and expenditure account was £11,993. During the year 2227 patients were treated at the hospital, 20,000 at the out-patient department, and 317 sent to the convalescent home at St. Anne's. The annual return of patients admitted to the Royal Infirmary during last year shows 10,997 new in-patients, 21,014 new out-patients, 18,305 new out-patients at the infirmary and central branch, and 1482 new patients at the convalescent hospital.

THE Liverpool and District Overseas Medical Officers are holding their third annual dinner at the Midland Adelphi Hotel, Liverpool, on Friday, Feb. 11th, when Sir John Goodwin, Director-General, A.M.S., hopes to be present. Tickets may be obtained from the honorary secretary, Captain G. F. R. Smith, 19, Queen's-drive, Mossley Hill, Liverpool.

DONATIONS AND BEQUESTS.—Under the will of the late Mr. D. M. Currie the following bequests, among others, are made: £20,000 each to Greenock Infirmary, Poplar, St. Thomas's, St. George's, St. Bartholomew's, Westminster, London, Middlesex, and Guy's Hospitals; £10,000 each to the Royal Scottish Corporation, Liverpool Infirmary, and Sir Gabriel Wood's Mariners' Asylum; £5000 each to the Liverpool Southern Hospital, Liverpool Caledonian Association, Belfast Infirmary, King's College Hospital, St. Mary's Hospital, and King Edward's Hospital Fund.—The Chelsea Hospital for Women has received from the Grocers' Company £50 towards building its nurses' home, and £12 18*s.* 9*d.*, proceeds *of an offertory from Chelsea Old Church.—Under the will* of Dr. Willoughby Furner, of Hove, who died in October last, £2,000 were bequeathed to the Royal Sussex County Hospital, Brighton, for the endowment of a bed in his name.—By the will of the late Mr. George Tangye, of Handsworth, Birmingham, £1,000 have been bequeathed to the Children's Hospital, Birmingham; £1,000 to the *Central Hospital, Birmingham: £1,000 to the Queen's* Hospital, Birmingham; and £1,000 to the Women's Hospital, Birmingham.—The late Mrs. Louisa Maria Borradaile, of St. Hilary, Lincoln, has left by will £500 to the Lincoln County Hospital.—Colonel Hendley Paul Kirkwood, late R.E., of Bath, among other bequests, has left by will £500 to the Royal United Hospitals, Bath.

WEST SUSSEX CORONERS' ALLOWANCES AND SALARIES.—*The West Sussex County Council* on Dec. 31st, 1920, passed resolutions revising the salaries and allowances of the coroners for the Horsham and Chichester districts. For the Horsham district coroner special allowances of £104 per annum were granted, and for the Chichester district coroner the sum of £25, the latter district not entailing such a large amount of railway travelling as the *former. The salary of the Chichester district coroner was* increased from £101 to £125.

SUSSEX PROVIDENT SCHEME.—The following scheme is set out by Dr. Gordon Dill, senior physician to the Royal Sussex County Hospital. Residents in Sussex, who pay the annual subscription—£1 per annum for a single member, £1 10*s.* for a married couple without children or a widow or widower with one child, and £2 for married people with children—will obtain a number of valuable benefits at present out of their reach. The scheme does not aim at providing ordinary medical attendance or at giving benefits supplied by the State or local authorities, but the medical attendants of members will be able to arrange for private consultations at the following *hospitals:* Royal Sussex County Hospital, Royal Alexandra Hospital for Sick Children, *Brighton and Hove Hospital* for Women (for Obstetrics and Gynæcology), Brighton and Hove Provident Dental Hospital (for Dental Surgery), Brighton, Hove, and Preston Dispensary, Sussex Eye Hospital (for Ophthalmic Cases), Sussex Throat and Ear Hospital (for Diseases of the Throat, Nose, and Ear), Lady Chichester *Hospital (for borderland Mental* Cases), and New Sussex Hospital for Women and Children. Any treatment found to be necessary as the result of this consultation will be given at the hospital, while patients confined to bed will be visited by consultants at their homes. At the Dental Hospital members will receive ordinary dental treatment, and dentures will be supplied at hospital rates. All the resources *of the Stephen Ralli* Memorial Laboratory at the Royal Sussex County Hospital will be available, including bacteriological and pathological investigations, vaccines, and X ray examinations and treatment; also massage and electrical treatment. All who are insured under the National Health Insurance Acts will come within the scope of the scheme, and for others a maximum *income limit of £260 for single members,* £400 for married people without children, or a widow or widower with one child, and £500 for a family are suggested. All subscriptions received during the year will be divided among the coöperating bodies in proportions which have been already agreed upon for the first year; but this arrangement—as also the rates of subscription except in case of *original members*—will be subject to revision in the light of the year's experience. The first 10,000 members will receive an "original member's" card, and their subscription will not be raised while they continue to be members. The scheme is already at work and members have been elected to it. Forms of applic*ation for membership may be* obtained at 4, St. George's-place, Brighton.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Jan. 18th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for Election to the Fellowship. (Names already circulated.)

MEETINGS OF SECTIONS.

Tuesday, Jan. 18th.

SECTION OF THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
LABORATORY MEETING at the National Institute for Medical Research, Hampstead, by the invitation of Dr. H. H. Dale (two minutes' walk from Hampstead Tube Station).
Presidential Address:
Dr. H. H. Dale: Recent Tendencies in Chemo-therapy.
Paper:
Dr. J. H. Burn: A Comparison of Digitalis Tinctures by Different Physiological Methods.
Demonstrations.

SECTION OF PATHOLOGY: at 8.30 P.M.
Communications:
Sir George Lenthal Cheatle: Carcinoma of the Breast.
Dr. J. A. Murray: Multiple Nodular Hypertrophy and Early Carcinoma in the Mouse Mamma.
Mr. A. H. Drew: *Amitosis and Mitosis in in vitro* Cultures of Normal Tissues and of Tumours of the Mouse.

Wednesday, Jan. 19th.

SECTION OF HISTORY OF MEDICINE: at 5 P.M.
Papers:
Dr. O. C. Gruner: *The De Viribus of Avicenna; the Key to the* Interpretation of the Arabian Theory of Medicine.
Dr. W. J. Turrell: The Electrotherapists of the Eighteenth Century. John Wesley, Paul Marat, and James Graham.

Thursday, Jan. 20th.

SECTION OF DERMATOLOGY: at 5 P.M. (*Cases at 4.30 P.M.*)
Case:
Dr. H. W. Barber: Severe Case of Tertiary Syphilis.
Other cases will be shown.

Friday, Jan. 21st.

SECTION OF OTOLOGY; at 5 P.M. (Cases at 4.45 P.M.)
Paper:
Mr. T. Ritchie Rodger: Cavernous Sinus Thrombosis—Notes of Four Cases.
Cases will be shown by—
Mr. Colledge, Mr. Jefferson Faulder, Mr. A. J. Hutchison, Mr. Harold Kisch, and Mr. Mollison.

SECTION OF ELECTRO-THERAPEUTICS: at 8.30 P.M.
Paper:
Dr. W. J. Turrell: The Therapeutic Activity of the Galvanic Current. To be followed by a discussion.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W.
TUESDAY, Jan. 18th.—8.30 P.M., Paper:—Dr. H. G. Sutherland Medical Evidence in the Staunton Murder Trial.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
MONDAY, Jan. 17th, WEDNESDAY, AND FRIDAY.—5 P.M., Hunterian Lectures:—*Prof. A. Keith: The Principles of Human* Craniology (illustrated by specimens and preparations) (Lectures I., II., and III.)

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, Jan. 17th.—12.15 P.M., Dr. Burnford: Pathological Demonstration. 2 P.M., Dr. G. Stewart: Medical Out-patients. Mr. D. Armour: Operations. 5 P.M., Lecture:—Dr. A. Saunders: *The Digestive Disturbances of Infants* and Children.
TUESDAY.—10 A.M., Mr. Steadman: Dental Department. Dr *McDougal: Electrical Department. 2 P.M., Dr. Pernet: Skin* Department. 5 P.M., Lecture:—Dr. Burnford: Physiology of the Digestive Tract.
WEDNESDAY.—11 A.M., Mr. MacDonald: Demonstration of Cystoscopy. 2 P.M., Mr. Gibb: Eye Department. Dr. Morton: X Ray Department. 5 P.M., Lecture II.:—Dr. Simson: Obstetric Emergencies.
THURSDAY.—2 P.M., Mr. B. Harman: Eye Department. Mr. Baldwin: *Orthopædic Department.* 2.30 P.M., Dr. A. Saunders: Demonstration of Cases (Medical Wards). 5 P.M., Lecture-Demonstration: Prof. H. Littlejohn: The Medico-legal Post-mortem Examination of a *Newly-born Infant* (open to all medical practitioners).
FRIDAY.—9.30 A.M., Dr. G. Stewart: Neurological Demonstration. 2 P.M., *Mr. Banks Davis: Diseases of* the Throat, Nose, and Ear. 2.30 P.M., Mr. Addison: Visit to Surgical Wards. 5 P.M., Lecture II.:—Mr. Baldwin: Appendicitis.
SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., *Dr. Owen:* Medical Out-patients.
Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

MIDDLESEX HOSPITAL MEDICAL SCHOOL.
THURSDAY, Jan. 20th.—3 P.M., Address:—Sir James Kingston Fowler: The Colonial Medical Service.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.
MONDAY, Jan. 17th.—5.30 P.M., Post-Graduate Lecture:—Dr. B. T. Parsons-Smith: Mitral Stenosis.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.

Post-Graduate Course on Infant and Child Welfare.

TUESDAY, Jan. 18th.—10.30 A.M., Dr. E. Pritchard: Practical Demonstrations on the Management and Feeding of Infants and Young Children—Demonstration I., Causes of Infant Mortality.

THURSDAY.—3 P.M., Demonstration II., How to Establish an Infant Welfare Centre and Conduct an Infant Consultation.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

THURSDAY, Jan. 20th.—3 P.M., Lecture:—Dr. A. Harden: Biochemistry.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Jan. 18th.—4.30 P.M., Lecture:—Dr. E. S. Reynolds: Aphasia.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately

THURSDAY, Jan. 20th.—4.30 P.M., Dr. Langley: The Diagnosis of Diseases of the Liver. (At Salford Royal Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

FRIDAY, Jan. 21st.—4.30 P.M., Dr. Lapage: Vomiting in New-born and Young Infants.

Appointments.

KENDREW, A. J., M.B., B.S Lond., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Barnstaple.

Hampstead General and North-West London Hospital: HUDSON, F., M.B., B.S Lond., House Physician; FULTON, R. H., M.B., Ch B. New Zealand, House Surgeon; LAWRENCE, G. S., M.B., Ch.B. Aberd., Casualty Medical Officer; MILLER, W. A., M.B., Ch.M. Edin., Casualty Surgical Officer.

Women's Medical Service in India: LEACH, F., Medical Officer in Charge of Dufferin Hospital, Cawnpore; WATTS, A. M., Medical Officer in Charge, Dufferin Hospital, Lucknow; GHOSH, L. M., Medical Officer in Charge, Ishwair Memorial Hospital, Benares

Vacancies.

For further information refer to the advertisement columns.

Altrincham General Hospital, Cheshire.—H.S. £175.

Bath, Royal United Hospital.—H.S. and H.P. £200 each.

Birmingham City Education Committee.—Asst. Sch. M.O. £500

Blackburn and East Lancashire Royal Infirmary.—Second and Third H.S.'s. £250 each.

Board of Education.—M.O. £600.

Bradford City, Infants' Clinic and Hospital.—Female Asst. M.O. £450.

Bradford Municipal General Hospital, St. Luke's.—House Res. Asst. M.O. £350.

Bradford Royal Infirmary.—H.S. £200.

Canterbury, Kent and Canterbury Hospital.—Res. M.O. £175.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £100.

Colchester, Severalls Mental Hospital.—Asst. M.O. £510

Durban, Government Hospital.—Asst. M.O. £484.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. M.O. £200.

Eccles and Patricroft Hospital.—Res. H.S. £200.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Female Dent. S. to In-patients. £10 10s.

Evelina Hospital for Children, Southwark, S.E.—Hon. P. to Out-patients.

Glamorgan County Council.—M.O. £700.

Great Northern Central Hospital, Holloway, N.—Cas. O. £200. H.S. £150. Anæsth. £10 10s.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—Hon. Dent. S.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. Res. M.O. £150. Also H.P.'s.

Hospital for Sick Children, Great Ormond-street, W.C.—Ophth. S.

Hull Royal Infirmary.—Asst. H.S. £150.

India, Countess of Dufferin Fund.—Three Med. Women. Rs. 350 per mensem.

Kettering and District General Hospital.—Res. M.O. £300.

King's College Hospital, Denmark Hill, S.E.—Clin. Pathol. £400.

Kirkburton, Storthes Hall Asylum, near Huddersfield.—Asst. M.O. £450.

Leeds Public Dispensary.—Res. M.O. £200.

Lincoln County Hospital.—Jun. H.S. £150.

Liverpool, David Lewis Northern Hospital.—Hon. Asst. M.O. to X Ray Dept.

London County Mental Hospital Service.—Seventh Asst. M.O. £300. Also Clin. Assts. £200.

London Homœopathic Hospital, Great Ormond-street, Bloomsbury, W.C.—Asst. P.

Macclesfield, Cheshire County Asylum, Parkside.—Asst. M.O. £350.

Manchester, Ancoats Hospital.—H.S. £150.

Manchester, Barnes Convalescent Hospital, Cheadle.—Res. M.O. £300.

Manchester Royal Infirmary.—Accident Room H.S. £200.

Manchester, Victoria Memorial Jewish Hospital, Cheetham.—Res. M.O. £150.

Middlesex County Council.—Asst. M.O. £500.

Newark Hospital and Dispensary.—Res. H.S. £200.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Anæsth.

Nottingham General Hospital.—Res. Cas. O. £300. H.S. £200.

Oldham Royal Infirmary.—Third H.S. £200.

Plymouth, South Devon and East Cornwall Hospital.—H.P. £150. S.

Prescot Union.—Non-res. Asst. M.O. £450.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. S. Also Ophth. S.

Queen Mary's Hospital for the East End, E.—Hon. Dental S.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. £150. Also Res. H.P. £125.

St. Mary's Hospital Medical School, Paddington, W.—Lecturer on Chemistry. £400.

St. Marylebone General Dispensary, 77, Welbeck-street, Cavendish-square, W.—Hon. P.

Salisbury General Infirmary.—Asst. H.S. £150.

Sheffield Royal Hospital.—Asst. Cas. O. £150.

Southend-on-Sea County Borough.—Asst. M.O. £500.

South London Hospital for Women, South Side, Clapham Common, S.W.—Female Asst. Path. £150. Anæsth. 10s. 6d. per attendance. Clin. Assts. H.P. and H.S. £100.

Stockport Infirmary.—Asst. H.S. £220.

Stoke-on-Trent and Stoke Rural Joint Hospital Board.—Res. M.O. £500.

Stoke-on-Trent, North Staffordshire Infirmary.—H.S. £200.

Stroud General Hospital.—H.S. £200.

Taunton and Somerset Hospital.—Res. Asst. H.S.

University of London.—External Examiners.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.P. and H.S. £100.

Wells Asylum, Somerset.—Asst. M.O. £300.

West London Hospital, Hammersmith-road, W.—P. Also Hon. Obstetric Registrar.

Westmorland Sanatorium and Home, Meathop, Grange-over-Sands.—Temp. Res. Asst. M.O. £7 7s. per week.

Willesden Hospital.—Additions to Hon. Med. Staff.

THE Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for the Sheriffdom of Stirling, Dumbarton, and Clackmannan. Applications for the post should be addressed to the Private Secretary, Scottish Office, and should reach him not later than Feb. 5th, 1921.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Arundel and at Long Buckby.

Births, Marriages, and Deaths.

BIRTHS.

MILLER.—On Jan. 8th, at 32, Abercorn-place, N.W. 8, to Dorothy wife of Dr. Reginald Miller, F.R.C.P. (of 110, Harley-street, W.1) —a daughter.

MOTT.—On Jan. 9th, at Glenlyon, Parkstone, Dorset, the wife of R. Culver Mott, M.B., of a daughter.

PATEY.—On Jan 8th, at Dagenham House, Newton Abbot, the wife of Walter Patey, M.D., of a daughter.

MARRIAGES.

DANE—NEWMARCH.—On Jan. 7th, at Havant, Robert Dane, M.R.C.S., L.R.C.P., to Ethel Margaret, daughter of the late John Newmarch and the late Mrs. Newmarch, of Howden Lodge, Southsea.

PARSONS—DAWNAY.—On Jan. 3rd, 1921, at the Church of St. Mary-le-Park, Battersea, Christopher Thackray Parsons, O.B.E., M.D. Lond., to Annie Burgess, widow of Archibald Hugh Payan Dawnay, F.R.C.S.

DEATHS.

BOUSFIELD.—On Jan. 7th, at De Crespigny-park, Denmark Hill, S.E., Edward Collins Bousfield, L.R.C.P., M.R.C.S., D.P.H. (Camb. and Lond.), aged 65 years.

HIGGENS.—Suddenly, on Dec. 28th, 1920, Charles Higgens, Consulting Ophthalmic Surgeon, Guy's Hospital.

HOWARD.—On Jan. 9th, at Green-street, W., Robert Jared Bliss Howard, F.R.C.S.

KINCAID PITCAIRN.—On Jan. 8th, at Richmond, Surrey, as the result of an accident, George Kincaid Pitcairn, M.B., C.M. Edin.

SOUTHWELL.—On Jan. 6th, at Hill-street, Stoke-on-Trent, Charles Edward Southwell, L.R.C.S. & P. Edin.

VASEY.—On Jan. 7th, at Bromley, Kent, Samuel Archibald Vasey, F.I.C., F.C.S., in his 55th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

SOME BIOLOGICAL ASPECTS OF DISEASE.

An Abstract of a Lecture delivered under the auspices of the Chadwick Trust, on Nov. 25th, 1920, by
Professor J. B. FARMER, F.R.S.

IN his introductory remarks the lecturer said that he proposed to dwell on certain peculiarities or properties of the higher organisms with which healthy and normal discharge of function is intimately connected. The illustrations of the points raised in the lecture were largely chosen from examples drawn from the plant kingdom, partly because from an experimental point of view plants were more readily accessible than animals, and also partly because the things of most fundamental importance were those which are common alike to animals and plants.

Interaction of Parts of an Organism.

Although our knowledge as yet was but relatively small, an outstanding fact was that one part of the organism could, and habitually did, influence other parts, limiting and directing their possibilities of growth and determining the particular mode of development which would be actually followed in any given individual. It was shown by means of a number of examples drawn from the study of plants, and supplemented by others from animal life, how the organisation of an individual depended on the mutual influence of its constituent cells one upon another. The coördinated growth which led to the development of a particular form depended on the serial (or sequential) nature of the reactions which went on in the cells and tissues of the organism. An intelligent recognition of this fact and of its consequences was essential to a proper appreciation of the larger problems both of health and disease; for anything which could modify the chemical changes concerned in the production of a "normal" organ or tissue was reflected in a departure, to a greater or less extent, from the particular form or structure normal for that organ or tissue.

Modification of Organisms by External Conditions.

The lecturer then went on to show, by consideration of a number of selected examples, how differences in chemical or physical environment might produce definite changes in the organism subjected to them. He further insisted that it must not therefore be concluded that only the external conditions mattered; a closer analysis of the facts emphasised the essential point that only when the environment was able to interfere at all, so to speak, with the protoplasm itself could a response of the kind indicated be obtained. In other words, the course of development in any given cell, or in any given individual, was only subject to modification by external conditions in so far as it was itself susceptible to influence by those conditions. For, on the one hand, the effects of temporary isolation of parts of the body from the material influences exerted by adjacent parts might result in a permanent loosening of those ties which previously served to knit the constituent cells into a coherent organism. On the other hand, union of parts hitherto separate might result in the formation of a synthetic new organism, different from those from which it—the new organism—had been built up. Lichens afforded a striking illustration of this fact. Other illustrations were provided in the new relations that are so commonly established between fungi and roots or other parts of the higher plants. Further aspects of the matter were opened up by a consideration of the various abnormal growths which could definitely be traced to the substances injected by parasitic animals, and a study of the formation of vegetable galls afforded a suggestive outlook on the consequences of the mutual relations here established between parasite and host.

From the foregoing considerations and conclusions, the lecturer passed on to a brief discussion of those various abnormal growths, or neoplasms, which originate as the result of obscure changes taking place within the cells themselves.

Cancer.

The normal course of events which produced and maintained what is called organisation could be upset in various ways. How did this circumstance affect our outlook on the mysterious disease which we called cancer? The fundamental fact was that certain body cells broke away from that coördinating elusive influence which controls normal development. The change is accompanied by cellular and nuclear modification, some of which had already been recognised, others perhaps not as yet. As Sir W. Collins had long maintained, no specific causal organism, so far as is known, is responsible for the incidence of cancerous development; probably various stimuli are able to effect that wonderful change. The result, however, was always the same—freedom from that control which is essential for the maintenance of an organised cell community. The tissue often exhibited rapid cell multiplication, which accompanied the newly acquired independence, and might lead to transplantations or metastases of cells which had been derived from the original cancer cells. This occurred in varied degrees, and the cells themselves might still retain, to some extent, the form and qualities of the typical tissue cells in which the change first appeared. The characteristic effect, however, always seemed to be to produce a more generalised type, recalling in some measure that of the lower organisms. An essential fact was that these transplanted cancerous units did not infect the tissues in which they came to lie, though they might, and often did, produce changes in the growth of the tissues, leading to the formation of the stroma.

The circumstance that this kind of tissue could rise from once normal cells, as the indirect result of stimuli of various kinds—e.g., continuous irritation and inflammation, the effects of lesion or of other less clearly ascertained precursory conditions—served to emphasise the need of a much more thorough biological examination than had hitherto been made. A suggestive example which showed how the protoplasm could change its behaviour under certain conditions was furnished by the events in the life-history of a myxomycete. These small organisms started life as a number of independent amœbiform cells, each with its own power of movement and growth. By-and-by a number of these fused to form a protoplasmic living mass of slime, which then behaved as a lowly but really organised entity, capable of feeding upon various nutritive substances. The coalescence of the individual amœbæ to form the plasmodium was followed immediately by the fusion, in pairs, of nuclei. As soon as this had taken place no more amœbæ were admitted as partners into the new cell republic, but any that approached sufficiently near it were drawn in and devoured.

Survey of the Present Position.

Although the cancer problem still remained for the most part (and from the point of view of its victims entirely) an unsolved one, it could nevertheless be attacked with a fair chance of success; but failure seemed to be inevitable, unless the right measures were adopted in attacking it. Surveying the present position we might well ask how much have we actually found out, how much nearer we were to the understanding of the causes which bring about these far-reaching changes in previously normal body cells—changes which endowed them with such appalling qualities. It had been discovered that the cell nuclei exhibited remarkable modifications; that those wonderful structures the chromosomes had undergone suggestive alterations both in number and in form. This in itself was a step in the right direction, and the lecturer believed we were justified in correlating the nuclear changes with the new properties acquired by the cells individually—in other words, that there was a causal nexus between nuclear change and functional disturbance. But if we were asked what started these complex changes in the cell nuclei, we should have to answer that as yet we did not know. The older assertions as to the existence of specific parasites, whether bacteria, yeasts, protozoa, or even helminthines, had not stood the test of closer examination. The more hopeful line of investigation seemed to point in the direction of chemical or physico-chemical disturbances, which might act in various ways and themselves be traceable to more than one source; but the *result* was clear, so far as it is known up to the present time. The cells so affected passed through certain definite changes, and became freed from those coördinating influences by which their chemical processes were previously regulated, and by which their multiplication had previously been held in check.

Such a complex problem as that of cancer was not likely to yield up its secrets till it had been broken down into the smaller components of which it constituted the formidable sum. The smaller problems must then be systematically attacked, and upon their solution the issue of the whole matter would finally depend. It appeared to be clear that success could only be reasonably looked for if the new investigations were planned from the first on sound general lines and placed in the hands of the very ablest men who could be found for the purpose. In spite of the dangers and difficulties lying in the way of organising research, the latter could be organised if wisdom, and not merely administration, ruled. Indeed, it had already been found practicable in dealing with other scientific problems or groups of problems, though on a relatively smaller scale.

General Nature of Required Research.

We should, for example, need to know far more than was known at present as to the precise nature of those influences which, by controlling individual cellular activities, made possible the existence of an organism. In certain directions actual progress had already been made—for example, in the case of some internal secretions. Tasks such as these would fall naturally within the province of the physiologist and of the bio-chemist, both on the plant and on the animal side. Extensions into the region of comparative experimental research on the physiology and bio-chemistry of the lower organisms were also clearly indicated.

Far more must be known, also, of the minute cellular changes which were involved; this would fall within the scope of the cytologist. Furthermore, all that assistance which the medical profession alone was in a position to render would be required, inasmuch as cancer was most common in the human species, and from a practical point of view it was really to this circumstance that the real urgency of concerted action was mainly to be attributed. In order that such research, based on concentrated and coöperative action, might be carried on with a prospect of fruitful results, it was essential to attract and retain the best men. Ample means must be forthcoming for this purpose. The task itself was so big that unless we were prepared to see it through on a liberal scale it seemed hardly worth while to proceed with it at all, for judging by past experience, little was to be expected from isolated efforts or from half-measures. The question was, were we prepared to go on watching the daily ravages of an unsparing foe in our midst, which continued still to strike, even as other diseases struck, till they were brought under reasonable control by means of scientific discovery, first as to their real nature and immediate cause, and thence by rationally devised checks on their onslaught. It was true that so far as we could judge, this problem was far more complex than they have proved to be. It might well be that a long time would elapse before malignant disease could be brought under effective control; we should do well not to be too sanguine or too impatient.

The lecturer here emphatically stated that he was far from undervaluing the work now going on at various institutions in this and other countries; but it seemed to him that the full magnitude of the task had not been sufficiently realised, and hence that the means which were essential to success had hitherto been lacking.

Outline of a Scheme.

Although, he continued, it was obviously neither practical nor useful then and there to attempt to formulate a detailed scheme, he would venture to outline the principles which he believed should be kept in mind. About a dozen first-rate men attached to research in the different relevant branches of science should be working in collaboration, and they ought to be provided with the means of attracting to their laboratories a number of able research students. Of course, there would be difficulties, but he did not think they were insuperable. In order that such men might be attracted and retained, they should be really well paid and their future secured to them. The funds should be provided by the State, for the work would be for the benefit of the whole community. A large sum would be needed; the interest on one million sterling would not be too much to cover the annual expenditure required by the scheme as the lecturer visualised it. But not much could be hoped for unless the country was prepared to shoulder the expense and provide for something much better than had heretofore existed.

THE DOCTOR'S FREEDOM OF SERVICE: THE AMERICAN VIEW.

A RECENT issue of the *Journal of the American Medical Association* devoted a long leading article to Mr. Ernest Hutchinson's play, *The Right to Strike*, drawn from the annotation columns of THE LANCET and from the letters of Dr. A. Cox and Dr. A. Welply, from which it is concluded that it was not a strike which was proposed but a "measure of reprisal." We mention the article here in order to call attention to an interesting ethical statement on the physician's freedom of service issued by the American Medical Association. It runs as follows:—

> A physician is free to choose whom he will serve. He should, however, always respond to any request for his assistance in an emergency or whenever temperate public opinion expects the service. Once having undertaken a case a physician should not abandon or neglect the patient because the disease is deemed incurable; nor should he withdraw from the case for any reason until a sufficient notice of a desire to be released has been given the patient or his friends to make it possible for them to secure another medical attendant. This question must be determined between the individuals who are primarily interested. It cannot be settled on the basis of principles governing the ethical relationships of groups.

In passing we remark on a curious inability to quote correctly. The "personal service" of our annotation is rendered quite inappropriately "professional services."

PORTEOUS "MAZES."

To the Editor of THE LANCET.

SIR,—In reference to your answer to "S. M. O." in your issue of to-day's date may I say that the Porteous "mazes" can be obtained from the C. H. Stoelting Company, 3037-3047, Carroll-avenue, Chicago, Illinois, U.S.A. Almost any kind of psychological apparatus can be got from this firm. And it is not creditable to British enterprise that, so far as I know, there is no firm in this country which acts as agent for this form of scientific goods. Apart from the trouble of ordering from, and remitting to, America, a British depôt would have the great advantage of enabling one to inspect some particular form of apparatus before purchasing it. It is annoying to purchase some form of test and then to find it unsuited for the particular purpose for which one wanted it.

I am, Sir, yours faithfully,
M. HAMBLIN SMITH.

H.M. Prison, Birmingham, Jan. 8th, 1921.

DISABLED officers and nurses who served during the war, along with the widows and dependants of deceased officers, can obtain advice and information regarding their rights under the regulations of the Ministry of Pensions by applying to the "Officers' Friend," Ministry of Pensions, Cromwell House, London, S.W. 1, or to the "Officers' Friend" at any of the regional offices of the Ministry—viz., Burton Court, Chelsea, S.W. 1., Newcastle-on-Tyne, Manchester, Bristol, Leeds, Nottingham, Birmingham, Edinburgh, Dublin, Belfast, or Cardiff.

Communications, Letters, &c., to the Editor have been received from—

A.—Association of Public Vaccinators of England and Wales; Capt. H. St. A. Agate, Portsmouth.

B.—Dr. J. Blomfield, Lond.; Dr. H. C. Brown, Lond.; Mr. H. W. Barwell, Lond.; Dr. A. D. Bigland, Wengen; Dr. H. C. Bazett, Oxford; Dr. W. Brown, Lond.; Dr. G. Blacker, Lond.; Mrs. C. Brereton, Lond.; Prof. A. E. Boycott, Radlett.

C.—Canadian United Manufacturers' Agency, Lond.; Chelsea Hospital for Women, Lond.; Messrs. J. and A. Churchill, Lond.; Prof. E. L. Collis, Cardiff; Mrs. A. Cunningham, Macclesfield; Dr. C. Coombs, Bristol; Dr. F. G. Clemow, Constantinople; Miss G. Cowlin, Lond.; Dr. H. M. Cade, Ipswich.

D.—Dr. H. A. Des Vœux, Lond.; Lt.-Col. A. M. Davies, R.A.M.C.; Dr. W. F. Dearden, Manchester; Dr. C. Daniel, Bucarest; Dr. J. Donald, Leicester.

E.—Dr. C. L. Evans, Lond.; Mr. J. T. Edwards, Lond.

F.—Sir J. K. Fowler, Lond.; Mr. H. A. T. Fairbank, Lond.

G.—Sir J. Galloway, Lond.; Dr. R. P. Garrow, Lond.

H.—Dr. D. C. Hare, Lond.; Mr. C. A. Hill, Lond.; Home Office, Lond.; Mr. J. T. Henderson, Pietermaritzburg; Mr. A. K. Henry, Dublin; Dr. T. S. Higgins, Lond.; Harveian Society, Lond.; Dr. A. M. Hervey, Paris; Col. C. B. Heald, Lond.

I.—*Indian and Eastern Druggist*, Lond.; Illuminating Engineering Society, Lond.

J.—Sir R. Jones, Liverpool; Dr. C. E. Jenkins, Manchester; Messrs. Jordan and Sons, Lond.

K.—Prof. A. Keith, Lond.; King Edward's Hospital Fund for London.

L.—Liverpool Medical Institution; London Dermatological Society; Dr. R. B. Low, Lond.; Prof. J. A. Lindsay, Belfast; Dr. N. C. Lake, Lond.

M.—Manchester Royal Infirmary; Mr. M. S. Monier-Williams, Lond.; Sir P. J. Michelli, Lond.; Maudsley Hospital Pathological Laboratory, Lond., Director of; Dr. J. W. McNee, Lond.; Dr. E. Morton, Lond.; Mr. J. Morgan, Cardiff.

N.—National Hospital for Diseases of the Heart, Lond., Sec. of; Dr. J. T. C. Nash, Norwich.

O.—Oxford Medical Publications, Lond.

P.—Dr. R. H. A. Plimmer, Aberdeen; Dr. H. R. Prentice, Lond.; Dr. M. Ponzio, Turin.

Q.—Queensland, Inspector of Hospitals for the Insane of, Brisbane.

R.—Royal Institution of Great Britain, Lond.; Royal Chest Hospital, Lond.; Dr. J. Reynolds, Lond.; Royal Society of Arts, Lond.; Research Defence Society, Lond.; Dr. D. G. Rice-Oxley, Lond.; Dr. J. D. Rolleston, Lond.

The Bradshaw Lecture

ON

THE SURGERY OF THE SPLEEN.

Delivered before the Royal College of Surgeons of England on Dec. 6th, 1920,

BY SIR BERKELEY MOYNIHAN, K.C.M.G., C.B.,
M.S. LOND., F.R.C.S. ENG.,
SENIOR SURGEON, LEEDS GENERAL INFIRMARY; PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF LEEDS.

IT was known to the ancients, and their knowledge has been confirmed in all later times, that the spleen is not essential to life. Aristotle wrote: "It is the position of the liver on the right side of the body that is the main cause for the formation of the spleen; the existence of which thus becomes to a certain extent a matter of necessity in all animals, though not of very stringent necessity." Erasistratus took the view that the spleen was wholly devoid of use. Galen spoke of it as an organ "full of mystery." In an old English translation by Holland of the "Natural History" of C. Pliny (23 to 79 A.D.) the following statement is found:—

> "*This member hath a proprietie by itself sometimes, to* hinder a man's running: whereupon professed runners in the race that be troubled with the splene have a devise to burne and waste it with a hot yron. And no marveile: for why? They say that the splene may be taken out of the body by way of incision, and yet the creature live nevertheless: but if it be man or woman that is thus cut for the splene, he or she looseth their laughter by the means. For sure it is that intemperate laughers have always great splenes."

Up to the last few years the operation of splenectomy was reserved *for cases of injury, for spleens with a* rotation of the pedicle, for cysts of the spleen, or for cases of enlargement of the organ due to causes which were not always discoverable. In the last few years splenectomy has been performed in certain of the anæmias associated with splenomegaly.

THE PATHOLOGY OF SPLENIC DISEASES.

The pathological changes found in the spleen can best be grouped according to the affinities which exist between the causative agents and the various parts of the spleen-liver system which they directly affect.

1. In the first type the provocative agent excites either a *mechanical effect or a local lesion of the exact kind pro*duced in other organs. The results will be expressed by the formation of an abscess, by a deposit of tuberculous nodules, by a metastatic new growth, and so forth.

2. In the second type an organism lodges firmly in the pulp of the spleen without actually producing a gross lesion there. Like any irritant of chronic character, it induces changes in the reticulum akin *to*, or *actually* constituting, fibrosis. The best example of this condition is afforded by the *chronic malarial spleen*, wherein, according to *modern* experience, the parasites lie apparently inert for long periods, to appear from time to time in the general circulation as a consequence of some excitant, suspected or unknown. The tropical splenomegaly may be regarded as a similar example, since here also the parasites are found embedded in the splenic pulp. It is probable that many *other chronic enlargements of the spleen may be regarded* in the same light, and it seems not unlikely that spirochætal infections, whether syphilitic or of an unknown type, may account for many forms of fibrosis and of chronic diseases. The work of W. J. Mayo on cases of splenomegaly associated with incoercible manifestations of syphilis is referred to elsewhere.

3. The third type of process is that which is set in motion by toxic substances reaching the spleen from some nidus *elsewhere in the body. Foci in the mucosa or submucosa* of various parts of the alimentary canal, in which there is no frank suppuration, but merely a subacute inflammatory cell-infiltration of slight or moderate extent, are easily overlooked, especially in the examination of the dead body. In pernicious anæmia, of course, definite lesions of this kind have been discovered by means of a special technique, and have been considered by Hunter, who first recognised them, *as the portal of entry of the causative infection.*

Given the primary infected lesion, the course of the toxic substances continually poured out into the vascular system is identical (for a part of the circuit) with that of the blood through the spleen, liver, and bone marrow. The toxic substances may be of various kinds, which may be named *according to their action.* They may remain in the blood-stream and act on the floating cells, or they may pick out certain tissues of the body. The *selective power of streptococci* (as shown by Rosenow) and of toxins is well recognised, and *mutual affinity of soil and seed may also be present.* There is nothing impossible, therefore, in conceiving *that some toxins will affect the cells of the spleen-pulp* exclusively, either causing degeneration in them, or *stimulating them to increased activity.* In either case the material which leaves the spleen may consist not *only of the original toxin, but also of the products of* degeneration or over-activity of the existing splenic cells. The poison contained in the blood leaving the spleen comes almost at once into contact with the blood from the stomach and the tail of the pancreas. In this way it may become altered enough to cease to have any deleterious action upon the cells next encountered—namely, the Kupffer star-cells and the other endothelial cells of the hepatic sinusoid, or the liver cell itself. On the other hand, the toxic substance or substances may arrive at the liver unaltered, and there set up changes in the respective elements which go to make up the unit of liver tissue. These changes are usually of a degenerative nature; but in some cases, owing to the toxins passing through the endothelium, reactive changes are excited in the fibre cells enclosing the lobule. This is the beginning of cirrhosis.

Another series of changes results when the brunt of the action of the poisonous substances is borne by the hepatic cell itself. As occurs in other parts of the body, the passage through the cell may cause no damage, but may provoke changes in the parts beyond; in this case in the smallest beginning of the bile-channel. Here the bile *itself may lose its fluidity, precipitates may form,* which in the minute channels cause blockage and a *mechanical biliary retention* (with or without jaundice). Or it may be that, without acting in any way upon the *bile, the noxious substances first affect the endothelial* lining of the bile-channels, and so set up some form of *cholangitis. In other cases, however, the liver cell is itself* affected, and a *series of clinical phenomena dependent on failure of the hepatic function takes place. After* that the stereotyped secondary cirrhosis may occur. *Leaving the liver the poisoned blood may pass through* the heart and lungs without losing its toxic character, *and may finally come in contact with the cells in the* sinusoids of the bone marrow, and interfere with their *function, if there is any affinity between them.* Where repression of function occurs, a certain type of anæmia results or a *diminution in the number of the white cells* which are being made there. Conversely, increase of white cells *may occur and leucocytosis form a con*spicuous feature.

Sufficient evidence has now been accumulated to enable us to form some idea of the varieties of toxins which may enter or leave the spleen; they are grouped according to their supposed actions: as causing anæmia, hæmolysis, asthenia with muscular wasting, cirrhosis of the liver, fibrosis of the spleen, or proliferation of various cells capable of active increase (for instance, in the germ centres of lymphoid follicles, or in the bone marrow in myeloid leukæmia). *Banti invoked the first* three types to explain the disease which goes by his name.

1. The most active *poisons causing anæmia* ("anæmising") are such as prevent the red cells from being formed. There is little doubt, however, that many substances are comprised in this group which produce anæmia *rather by destroying* the red cells or by rendering them vulnerable. In this case the phagocytes *of the spleen-pulp* become unduly active, and a complication is introduced, inasmuch as these pigment-laden cells carry their burden to the liver, disintegrate there, and overburden *this organ,* beside-

---

*Published in full in the British Journal of Surgery, January, 1921.

producing another and peculiar type of change—siderosis and proliferation of endothelial cells.

2. The *hæmolysing poisons* are important. They play the chief part in hæmolytic splenomegaly, and in some forms of severe anæmia, as well as in some special types of cirrhosis. Chevallier and Tourkine have been at much pains to insist on the dual character of the hæmolying poisons, some of these having the property of actually destroying the red cells, while the others only cause them to become "fragile."

3. *Poisons which excite fibrosis* are very common. The process of fibrosis has been long assumed to be merely the last stage of an inflammatory process; but there is evidence to show that fibrosis of the spleen may be a specific phenomenon, just as in the liver biliary cirrhosis is certainly the result of active and direct stimulation of the connective-tissue cells.

4. *The poisons which excite cell-proliferation* may concern the cells of the Malpighian bodies, as in lymphatic leukæmia and some kinds of Hodgkin's disease, or the cells of the spleen pulp. In the latter case several things may happen. The pulp cells may assume the properties usually restricted to the cells of the bone marrow concerned with the formation of white cells; in these circumstances bone-marrow cells are produced. If this should occur in a slight degree it is only revealed by microscopic examination. Instances of this action are afforded by various acute specific fevers. If it occurs in a greater degree the enlargement of the so-called splenomedullary leukæmia is brought about. Sometimes the pulp cells develop enormous numbers of cells of all kinds, and so produce a tissue of very complicated structure, as in lymphosarcoma or Hodgkin's disease.

THE CLINICAL AND ASSOCIATED PHENOMENA IN SPLENIC DISEASE.

The list of symptoms and signs likely to be encountered resolves itself into a short one when the mechanical results which follow upon a gross enlargement of the organ, or upon the obstruction to the portal circulation by a terminal cirrhosis of the liver, are omitted.

1. *Anæmia.*

Anæmia is caused by many diseases. In this connexion it is only necessary to consider the type of anæmia which rightly directs the attention of the clinician to the spleen as its cause. It may be asserted that a disease of the spleen is to be suspected when there is any evidence that hæmolysis is associated with anæmia. What exactly is the full significance of the term "hæmolysis"? It may be taken to indicate the occurrence in orderly succession of the following events: A destruction of the red cells, the accumulation of their remains in the spleen, the ingestion of these remnants by the phagocytic endothelial and reticular cells, and, finally, the transmission of these engorged cells to the liver, in whose "sinusoids" they are disintegrated preparatory to the absorption of their particles by the stellate cells of that organ. Hæmolysis will be rendered an easier, and therefore a more frequent process, if any diminution occurs in the resistance offered by the red cells to their destruction. Such a change has been described by Chauffard, who speaks of a "dystrophy" of the red cells, a condition in which their vulnerability is increased, and there is consequently a special "fragility." It has been asserted that the presence of a fragility of the red cells indicates that the seat of any disease in which it occurs is in the spleen; but there is evidence to controvert this opinion. Such a fragility might be due either to an early error in the formation of red cells by which there was an attenuation (through defective supply of the necessary material) of their lipoid component, or to the inimical effects of a substance produced by bacterial agencies in some lesion, perhaps quite inconspicuous, in the mucosa of the alimentary canal.

But every anæmia associated with disorders of the spleen is not characterised by hæmolysis. There is another important group of anæmias in which the initial disorder is either in the bone marrow (and in the later changes in the spleen) or is dependent upon the same cause as that which affects the bone marrow. When once the process of hæmolysis has developed to the stage described above, the further course of events will depend on the manner in which the liver cells cope with their increased burden. On the one hand, the poison (which has destroyed the red cells) may pass through the liver cells without affecting them; the extra load imposed upon them is borne without injury. On the other hand, the poison may actually injure the hepatic cells, so that the excess of blood pigment is disposed of with a steadily increasing difficulty. Then, at last, under a continued strain, the inadequacy of the liver may become apparent, either clinically in the form of jaundice, or pathologically by reason of the appearance of urobilin in the urine. The great functional capacity of the liver cell accounts for the gradual, insidious, and tardy onset of the symptoms connected with the involvement of the liver in such conditions. It is interesting to find that the clinical phenomena due to a hæmolysis are absent in those diseases in which the liver cell is equal to its work and does not suffer impairment. In the enlargement of Hodgkin's disease, of myeloid and lymphatic leukæmia, of sarcoma of the spleen, of lymphogranuloma, all the phenomena associated with hæmolysis are characteristically absent. But none the less anæmia develops. The reason is, no doubt, the following:—

With the exception of the leukæmias, where the energies of blood formation become overwhelmingly directed to the formation of white cells instead of red, these various diseases of the spleen are associated with progressive fibrosis; there is consequently a gradual interference with the normal capacity of the endothelial cells to remove effete red cells. This entails a loss of iron to the body. The liver cells do not receive sufficient iron in that form which is suitable for reconstruction in the next step of the cycle. Even if phagocytes in other parts of the body assume the function of red-cell destruction, they have not direct access to the liver, and cannot therefore supply this organ with sufficient speed or adequacy. It seems quite clear, from the experiments in connexion with iron metabolism, that the spleen is situated where it is in order to enable the iron-laden endothelial cells to have a free channel for their passage into the minute capillaries of the liver, through which they are too large to pass.

2. *Jaundice.*

When jaundice arises as the result of a toxic process in the spleen-liver system two matters require consideration. These are the site of action of the poison and the nature of the poison. In splenic anæmia there is no primary interference with the activity of the liver cells; it is only when cirrhosis develops in the latest stage that the cells become affected, and then only in an indirect manner by compression from without rather than from disorganisation within the cell. In hæmolytic splenomegaly, on the other hand, the liver cells from the first are either poisoned or burdened beyond their normal capacity for dealing with blood pigment. The remarkable tendency to cholecystitis and cholelithiasis in this disease suggests the passage of toxic substances into the bile, acting, perhaps selectively, upon the mucosa of the gall-bladder.

Jaundice does not necessarily appear, even though the process of disposal of blood pigment is inadequately performed. The absence of jaundice, that is to say, does not justify the opinion that in any particular patient the successive steps in the cycle of the metabolism of hæmoglobin which have been taken between the spleen and liver are normal. When the blood pigment is broken down it gives rise to two portions, one free from iron, the other containing iron. The former, undergoing purely intramolecular change, appears in the liver cell as bilirubin and passes out into the bile capillaries; the iron-containing portion makes its way back to the site of the manufacture of the red cells. In disease this story becomes modified, either at the first stage or at the second. The division of the blood pigment molecule may not take place; hæmatin is then formed and gives rise (it is supposed) to one of two substances (maleic imide, maleic anhydride), either of which being *colourless* will escape observation in the liver cell. Or, on the other hand, the iron-free substance formed from the blood-pigment molecule may not become converted into bilirubin, but into a hæmopyrrhol, which is also colourless. In this case also bile pigment fails to appear in the liver cells (and in the bile in the gall-bladder ?) and jaundice is not present. These considerations provide a suggestive basis for the explanation of the anomalies which appear from time to time in reported cases of cirrhosis associated with splenomegaly.

It has been stated above that the liver cells become affected when cirrhosis occurs. It is desirable here to emphasise the mechanism of the production of cirrhosis, for the story is hardly complete without some reference to the pancreas. If so much has been said about the inter-relations of the spleen and liver, and so little about the pancreas, it is because there is a wealth of positive information respecting the former. If the secretion from the tail of the pancreas (where the islands of Langerhans are most numerous) plays a necessary part in the intravascular changes which take place between the spleen and liver, attention would naturally be directed to a determination of the frequency with which interstitial pancreatitis, focal or diffuse, is associated with splenic disease. Unfortunately our information is slender and uncertain. The direct connexion between pancreatic disease and hepatic cirrhosis is at present clear only in one form of cirrhosis, the so-called "pigmentary cirrhosis." It may be that the cirrhosis begins merely as a consequence of the disturbance initiated in the spleen. It is clear that the presence of iron which is not in a suitable condition for reconstruction in the liver, aided by the direct action of a poison (modified by passage both through the splenic endothelium and the endothelial cells of the liver sinusoids), may excite an overgrowth of the fibre cells outside the liver lobules. If it should do so, not only will there be cirrhosis of the Laennec type, but there will also be a special form of pigmentary deposit. A purely hæmolytic poison, that is to say, has modified the process of disposal of blood pigment, in spite of its own modification by the splenic products into a cirrhogenic substance. It is certainly significant that in such cases the pancreas not seldom shows a widespread change.

3. *Petechial Hæmorrhages.*

These are occasionally seen in cases of splenic disease, in leukæmia, and in von Jaksch's disease. They always denote damage to the endothelial cells of the capillaries in various parts of the body by a particular form of poison, named "endotheliotoxin," because its effects are known and obvious, and because there is no adequate knowledge indicating its chemical constitution. The minute petechial hæmorrhages are scattered through many organs, appear on serous surfaces, and may occur on mucous surfaces, as in the nose and on the gums or in the kidneys. In these cases they almost certainly denote the channel of excretion of the poison by which they are caused. Such clinical phenomena, as is well known, sometimes accompany the circulation of certain septic organisms or of the toxins derived from them; they here signify a special property of the leukæmia and allied poisons.

4. *Muscular Weakness.*

This may be associated with an actual wasting of the muscle, which partly accounts for the emaciation noticeable in advanced cases of leukæmia and of splenic anæmia. When we remember the intimate association between the spleen and endocrine system the question arises as to the extent to which the phenomena of muscular weakness and asthenia are to be attributed to a direct action upon the adrenal or thyroid glands. The inter-relation of these endocrine glands with each other and with the glands possessed of external secretions is only now being revealed to us by the work of many observers.

5. *Pyrexia.*

Pyrexia as a feature of splenic disease has only recently attracted close attention. There is a tendency to ascribe fever appearing in the course of diseases, hitherto regarded as intrinsically apyrexial, to a secondary infection with septic organisms, especially when the temperature curve, as is frequently the case, is intermittent. In Hodgkin's disease pyrexia is almost constant, is indeed regarded by some clinicians as almost essential to a correct diagnosis. In pernicious anæmia pyrexia runs in waves spread over three, four, or more weeks, to be followed by apyrexial phases; in leukæmia there are also pyrexial periods. The question is raised at once as to whether each of these diseases may be of microbic origin. In hæmolytic jaundice fever occurs periodically; it is generally slight and lasts for two or three days. In other cases it is severe, but of shorter duration; the temperature rises abruptly, remains at its maximum a very brief period, and falls quickly. There is the characteristic "steeple" chart of cholangitis. In such cases stones are often, but not always, present in the common bile-duct.

6. *Splenomegaly.*

When the spleen is recognised, by any method of clinical examination, as being enlarged, it is certain that it is at least twice the normal bulk. Any enlargement less than this, and often even this, cannot be discovered by palpation or by percussion. Perhaps, taking an average of all cases, the very largest spleen is to be found in Gaucher's disease, the next largest is leukæmia, and the next in malaria, though occasional instances are found in this last disease in subtropical countries which surpass all others. Then comes a series in which the spleen is large, but not excessively so, and, finally, there are cases in which the spleen is not enlarged at all. Thus the spleen may be involved in Hodgkin's disease without being clinically enlarged; it is not always enlarged in pernicious anæmia, and its enlargement then bears no discoverable relationship to the gravity of the case. These aspects of the subject are so well known that this symptom is only referred to for the sake of drawing attention to the fact that an absence of enlargement of the spleen does not relieve this organ from the suspicion of being the source of a patient's illness.

7. *Leucocytosis.*

The significance of this phenomenon lies in the fact that it affords an insight both into the nature of the agent at work and into the state of those tissues which are concerned in the manufacture of the leucocytes. There are some toxic substances which expend their whole baneful power upon the circulating leucocytes; others affect their formative tissues; while a few may act upon both. The action exerted may be one of stimulation, so that leucocytosis results, or it may be one of inhibition and result in leucopenia. In pernicious anæmia the poisonous action on the bone marrow affects the white cells as well as the red, so that a very low white-cell count is the rule. In hæmolytic jaundice, on the other hand, the action on the bone marrow is one of stimulation, and leads to an increased outpouring of leucocytes. Where the poisonous substances act upon the pulp tissue of the spleen, upon the endothelium of the liver sinusoids, and upon the whole reticulo-endothelial system, exciting the dormant cells to form myelocytes (myeloid metaplasia), stray myelocytes can be found in the blood-stream. This occurs in some forms of acute splenitis, occasionally in Hodgkin's disease, notably in infantile splenic anæmia, and sometimes in pernicious anæmia. The same process occurs in massive fashion in leukæmia, where every part of the reticulo-endothelial system competes against the rest in the effort to produce and pour out these abnormal cells. The pulp tissue of the spleen then appears almost as a replica of ordinary bone-marrow tissue, and the immature cells pass freely into the blood-stream. In virtue of the character of these cells, which, strictly speaking, are not leucocytes, such a phenomenon should not be described as an extreme leucocytosis.

It is therefore not sufficient in any case of leucocytosis to determine merely the presence or absence of an increase in the number of white cells. It is necessary also to ascertain which varieties of cells are represented in the increase, and to recall the significance of each specific increase. An increase of the neutrophiles indicates the presence of toxins of nucleoprotein form, or of the products of dissolution of albuminous substances. An increase of lymphocytes denotes activity of poisons of lipoid character, with whose destruction these cells are especially concerned. The large mononuclear leucocytes are increased when the particles of abnormal matter are large enough to be microscopically visible. When the eosinophiles are increased it may be concluded that the poisonous substances have an affinity for the sympathetic nervous system, although the relation of these cells to the integrity of the nervous system is not the only one they possess. Poisons may accumulate in various tissues and set up local accumulations of these cells (as in Hodgkin's disease) and at the same time excite the bone marrow, the spleen, and the lymph glands to join in the over-production of these cells. The tubercle bacillus and the spirochæte of syphilis are well known to secrete lipoid substances; the association of lymphocytosis with these diseases is to be expected. That stimulation of the lymphocyte formation occurs in pernicious anæmia, splenic anæmia, and Graves's disease indicates the direction of the inquiry to be made into the ultimate causation of these diseases.

8. *The Spleen and the Hæmorrhagic Diathesis.*

During recent years the suggestion has been made that the spleen may in some degree be concerned with the life-history of blood platelets. In a patient suffering from purpura hæmorrhagica there is a decided diminution in the number of platelets, and the spleen is enlarged. After splenectomy the normal conditions are restored; in proportion as the number of platelets is increased so the clinical symptoms disappear. Cases illustrating this experience are recorded by Schmidt,[1] Benecke,[2] and Kaznelson.[3] The name "splenogenic thrombolytic purpura" has been given to this condition, and a "thrombocytolytic syndrome" is described. It is supposed that there is an increased destruction of platelets by the cells of the reticulo-endothelial system. If, however, the whole of this vast system is implicated, it is not easy to understand why extirpation of the spleen should cure the disease or relieve the patient of symptoms. Katsch[4] has reported cases of thrombopenia where there is no purpura; and, conversely, cases of purpura where the number of platelets is not diminished.

9. *Urobilin in the Urine.*

Recent work shows that the presence of this substance in the urine is an indication of functional inadequacy of the liver cell, which is accompanied by some degree of obstruction in the minute extracellular bile canaliculi. A certain quantity of bile escapes through the ducts, undergoes the usual transformation into stercobilin in the intestine, re-enters the liver, but cannot find a free exit through the hepatic cells. The significance of this phenomenon is that there is an increased breakdown of red cells and hæmoglobin, and that there is a state of cirrhosis in the liver; the degree of disturbance of function is in proportion to the degree of "fragility" of the red cells.

Viewed in this light, the next step to be followed, after arriving at a conclusion that the spleen is diseased, is to determine the degree of damage to the liver, and instead of regarding cirrhosis as a collective term for many distinct morbid entities, to view all cirrhoses as representatives of degrees of implication in the one morbid process.

PERNICIOUS ANÆMIA. ADDISON'S ANÆMIA. IDIOPATHIC ANÆMIA.

The work of the surgeons in the last few years has afforded some evidence, if not as to causation at least as to associated conditions, in cases of pernicious anæmia. N. M. Percy, whose work on this difficult disease has been marked by a most earnest devotion and remarkable success, has pointed out that since his attention was especially directed to the testing of Hunter's view of the infective origin of pernicious anæmia he has found evidence of infective foci in 95 per cent. of cases. In a consecutive series of 9 operations for pernicious anæmia, all specimens removed (spleen, gall-bladder, appendix) were sent at once for pathological examination. Bacteria were grown from 3 of the 9 spleens, from 4 of the 7 gall-bladders, and from 6 of the 7 appendices. The only case not giving a bacterial growth was one in which pyorrhœa had long been present. The chief organism found was the hæmolytic streptococcus (7 cases); in 5 the *Bacillus coli* was found; in 4 *Streptococcus viridens*. Smithies, of Chicago, has grown bacilli and cocci of the hæmolytic type from infected areas about the teeth, tonsils, and accessory sinuses. In a series of 24 cases, preceding the 9 just mentioned, Percy records the following gross lesions. In 20 there was chronic cholecystitis with or without gall-stones; in 17 of these there was evidence of old disease in the appendix; in 6 there were infective foci in connexion with the teeth, and in 1 in connexion with the tonsil.

Splenectomy in Pernicious Anæmia.

In the year 1913 three observers, Eppinger,[5] De Castello,[6] and Klemperer,[7] independently, and for different reasons, suggested the performance of splenectomy in cases of pernicious anæmia. The results, which were not long in coming, showed that the mortality of the operation was high, that the immediate benefit which not seldom followed was transient, that post-operative complications were frequent, and that, with few exceptions, the general course of the disease was not materially altered. That splenectomy alone might offer help seemed probable from the work of Robertson, who found, in cases studied by himself, that the rate and degree of hæmolysis in pernicious anæmia underwent a constant and marked decrease after removal of the organ. Largely owing to the work of W. J. Mayo and his most able band of colleagues, and of N. M. Percy, a wider view of the necessities of these cases was taken, with a great improvement in results. The anæmic condition of the patients was improved by transfusion of whole blood; and foci of infection, possibly "primary," but certainly co-existent, in the mouth or accessory sinuses, or in organs laid bare by the abdominal operation, were removed. The purpose of the extended operations consisted, as Percy said, of three main factors: (1) An attempt to stimulate the production of new blood by massive "step-ladder" transfusions of whole blood: (2) an attempt to overcome the absorption of hæmolytic bacteria or their toxins by the radical removal of local foci of infection; and; (3) an attempt to protect the newly formed and older red cells by removing the spleen. Each of these steps is important. The "step-ladder" transfusions bring about an elevation, step by step, of the quality of the patient's blood in respect of red cells, hæmoglobin content, &c.; they supply blood which is not only useful in itself, but acts also in a manner stimulating and nourishing to the bone marrow, encouraging it to still further efforts. The eradication of active foci of infection relieves the patient of a chronic toxæmia which is possibly an ætiological factor. The removal of the spleen reduces the abnormal amount of blood destruction. Discussion has recently ranged around the question as to whether transfusions frequently repeated are competent of themselves to produce an improvement in the patient's condition equal to that seen when both transfusion and splenectomy, or these two with the addition of the eradication of infective foci, are undertaken. Under what circumstances may these steps of treatment be taken? They are useless in the "aplastic type," and they are of little value, if any, in cases where cerebral or spinal symptoms are already present, unless the anæmia is profound, when transfusion alone may give some degree of transient benefit. In all other cases the repetition of a blood transfusion about every eight or ten days gives very striking results.

Dr. W. J. Mayo has very kindly given me the record of all cases of splenectomy performed in the Mayo clinic up to Sept. 20th, 1920. The following are the results in the cases of pernicious anæmia: There were 53 cases with 3 deaths, a mortality of 5·6 per cent.; 5 patients were living between four and five years after operation; 11 patients were living between three and four years after operation; 22 per cent. of patients lived two and a half times as long as the average. What may be said, then, of the efficacy of splenectomy in this disease? In the first place it cannot be claimed, and is not claimed, that any patient has been cured of his disease. The risks run in undergoing the operation are small, but not so insignificant that they can be ignored. A few lives are sacrificed. All the patients who survive are not benefited, but in the majority a degree of improvement results, and a prolongation of life, in greater comfort and with increased zest, can be recorded. The truth is approximately this: that as a result of repeated transfusions of blood, removal of the spleen, and eradication of all foci of infection, one-quarter of the patients are greatly improved, living happier and more useful lives, prolonged beyond the expectation by a period of two or three years; one-half of the patients are improved in some degree, they feel better, take nourishment better, sleep better, and live perhaps a few months, or even a couple of years longer than the average; the remaining one-quarter of the cases do not receive any help greater than that which could be derived from careful medical treatment, which may include the "step-ladder" transfusions of blood if these are found to be helpful, and the treatment of such foci of infection as can be found in the mouth, nose, or accessory sinuses. When the position is accurately stated to patients who suffer from this disease they are likely to decide the matter according to their temperaments. Surgeons should rarely, or never, urge operations, for they should rarely, or never, find it necessary to do so, if the problem to be decided is fully and honestly stated to a patient or his relatives. In cases of pernicious anæmia an operation is indicated for those who are found by such tests as I have mentioned to be likely to do well, and who are eager to get the most out of the remainder of their days and to prolong them.

LEUKÆMIA.

Leukæmia may be considered as a morbid process manifesting itself diffusely, and consisting of hyperplasia of various leucocytes—sometimes of the lymphocytes, sometimes of the myeloid cells scattered throughout the body. The severity of the degree of hyperplasia may be so great, and the type of cells produced may be such, that what is called a "sarcoid" process results. There are cases in which, however, the newly formed cells are found in the spleen, lymph-glands, and bone marrow, but do not enter the blood-stream; the blood on examination is normal. "Leukæmia," therefore, may be regarded as having two relationships: on the one side to the disease known as lymphosarcoma; on the other to Hodgkin's disease.

It was Pappenheim who elaborated the thesis that the virus at work may travel either by the lymphatic channels (producing a "lymphatic leukæmia") or in the blood-channels (producing a "myeloid leukæmia"), and that the purpose of an inquiry should be to ascertain the nature of the stimuli or irritants capable of exerting such effects.

Until recent years no treatment seemed to have any considerable effect in cases of leukæmia, but in 1912

Koranyi[8] observed the effects of benzol poisoning in girls working in a factory where benzol was used as a solvent for a rubber. The symptoms produced by this drug suggested to him the possibility of its use in the treatment of leukæmia. In reporting his experience he states that there were no failures with benzol in cases of chronic leukæmia; that the spleen and lymph nodes were little affected; that benzol given alone was of benefit, but, although more gradual in its effect than the X ray, it succeeded where this failed; and that patients responded better to benzol treatment after the spleen had been exposed to X rays. No serious ill-effects were observed to follow the treatment.

The application of radium produces the most astonishing effects in reducing the size of the spleen. As the spleen diminishes the general condition of the patient steadily improves, and the blood count approximates to the normal. In a very interesting paper Ordway[9] discusses the whole question of radium therapy very fully, and draws the following conclusions:—

> 1. Surface applications of radium in leukæmia produce striking, indeed remarkable, improvement in: (a) the blood picture, which becomes almost normal; (b) the size of the spleen and glands, which are reduced almost to normal; (c) the general condition of the patient, who, from being emaciated and weak, may become plump and strong.
>
> 2. The duration of the remission is variable; it may last from months to years.
>
> 3. The results of radium treatment are not regarded as curative. It is believed to be, however, the safest as well as the most prompt palliative measure in cases of chronic leukæmia, whether refractory or not to benzol or X ray treatment.

From the results of radium therapy in leukæmia it is believed to be the best form of treatment now at our disposal.

The mortality of splenectomy in these cases was so heavy that it was largely abandoned, but the removal of the spleen when reduced to normal size by radium is neither difficult nor so dangerous, and according to Dr. W. J. Mayo should be considered in selected cases.

[Sir Berkeley Moynihan then discussed the pathology of Hodgkin's disease, for which splenectomy was rarely necessary. He had performed only one such operation 22 months ago, and though the patient was still in good health and at work, it was very doubtful if the removal of the spleen had had any effect upon the progress of the disease.]

SPLENIC ANÆMIA. BANTI'S DISEASE.

Banti considered the disease as possessing clinically three stages, merging gradually into each other. These stages were: (1) One in which there was enlargement of the spleen and a secondary anæmia, the duration being 3 to 12 years; (2) one in which the liver gradually enlarged and the amount of urine underwent progressive diminution—the duration was brief; (3) one in which the liver gradually shrank in size and ascites appeared, the symptoms being those of an ordinary atrophic cirrhosis; the duration of this stage was between one and two years. The disease was invariably fatal, and death occurred either from hæmorrhage or from auto-intoxication from cirrhosis.

Clinical History.

Splenic anæmia was defined by Osler as "an intoxication of unknown nature characterised by great chronicity, primary progressive enlargement of the spleen which cannot be correlated with any known cause, anæmia of a secondary type with leukopenia, a marked tendency to hæmorrhage—particularly from the stomach—and in many cases a terminal stage with cirrhosis of the liver and jaundice." The clinical features of the disease then are the following:—

(1) A very chronic course; (2) a slowly progressive enlargement of the spleen; (3) changes in the blood (of the type found in secondary anæmia); (4) the tendency to hæmorrhages; (5) affection of the liver; (6) an unknown causation; and (7) other phenomena chiefly of negative importance.

The differential diagnosis from cases of gastric and duodenal ulcer, cirrhosis of the liver, and syphilitic enlargement of the spleen and liver is not, as a rule, difficult.

The Pathogenesis of Banti's Disease.

The fact of utmost significance in connexion with the causation of this disease is that it is cured or arrested by removal of the spleen. This fact may be accounted for either by assuming that the disease is primarily and essentially located in the spleen or by assigning to the organ the rôle of modifying the action of some agent situated elsewhere in the body.

If the disease is primarily splenic a search for a specific microbic infecting agent should ultimately be successful. Hitherto no convincing evidence of this has been found, although Hollins has argued strongly in favour of incriminating the colon bacillus. There is scope for further research in this direction, and the organ removed during life, if straightway examined, should provide profitable material for routine bacteriological investigation.

The enlargement of the spleen has been attributed to excessive hæmolytic activity by those who consider the disease to begin in some other part of the body. But such a view does not sufficiently explain the fibrosis which is the outstanding histological feature of the disease. A chronic infective process would account for the enlargement as well as the fibrosis, and accord better with the absence of undue hæmolysis of the red blood cells. In splenic anæmia the red cells never show "fragility." If there is a change the corpuscles may show increased rather than diminished resistance.

The anæmia, in like manner, may be regarded as an incident or as an essential part of the disease. Rolleston, a very distinguished authority, does not regard the anæmia as primary; he believes it to be secondary to attacks of very severe hæmorrhage, chiefly because he finds that regeneration of blood takes place after these events. This view, however, is, I think, subject to the criticism that such severe hæmorrhage is not invariable, and that the substance elaborated in the spleen need not be capable of affecting the bone marrow until after it has left the liver, where it has undergone modification. Further, whatever the poisonous substance may be, it need not completely arrest blood-cell development. A parallel case is, I think, sometimes furnished by subjects of leukæmia in which an intercurrent infection supervenes, with a temporary restoration of the normal blood-picture.

Hollins regards the disease as being due to an active "intoxication" produced by the colon bacillus, whose "colilysin" brings about the anæmia, whilst its actual presence in both spleen and liver accounts for the fibrosis of each organ. This view would put every kind of cirrhosis of the liver on the same level, because "colilysins" could not be expected to vary radically in their action. The facts would be better met were it suggested that the spleen harbours various organisms, some of which only excite a local fibrosis, others induce a simple cirrhosis of the liver, and still others produce that form of cirrhosis associated with Banti's disease, with a toxic anæmia and other specific symptoms.

In respect of the hæmorrhage which is so conspicuous and alarming a feature of some cases, Rolleston considers that the enormously distended vasa brevia rupture into the stomach as a result of the torsion of the splenic vein caused by the great bulk of the organ. This opinion is certainly correct in many cases. The hæmorrhage is so profuse and so swiftly escapes from the stomach that large vessels must be implicated. Such vessels as Rolleston describes are often seen in operations upon cases of splenic anæmia when abundant hæmatemesis has occurred. But this cannot, I think, be the whole explanation. The relationship between enlargement of the spleen and gastric hæmorrhage is cryptic, but certain; for, as Balfour was the first to show, removal of the spleen may cure a patient whose life has been jeopardised by severe and recurrent hæmorrhages from the stomach. Gastric hæmorrhage is known to be toxic in origin in certain cases, as, for example, those in which there is a lesion in the appendix, intestine, or gall-bladder; and those also in which the lesion lies in the spleen or liver, or both.

Treatment.

The only treatment for splenic anæmia is splenectomy. The appropriate moment for the removal of the organ is chosen. It is inadvisable to operate soon after a grave hæmorrhage, or when the spleen is extremely large. In the latter case the effect of radium on the tumour should be tried; almost certainly it will cause a rapid and considerable shrinkage in the organ. If this should happily be the case splenectomy is done when the spleen is at its smallest, and before it has begun to enlarge afresh, as it will certainly do after a few weeks. It is imperative to operate upon cases of this disease as early as possible. No other form of treatment needs consideration; the dangers and difficulties of the operation increase with the lapse of time; early operation means a more certain chance of recovery and a quicker convalescence. In the later stages the mortality of operation is higher, amounting to 25 per cent. as compared with an average of about 10 per cent. In the terminal stages operation becomes so dangerous that only the inevitably fatal outcome of the unhealed disease justifies its performance.

The degree of improvement that may take place is astonishing, even in the late stages of the disease, with advanced involvement of the liver. It is, as W. J. Mayo says, an evidence that the great power of the liver to regenerate its specific cells is utilised to the full.

The difficulties of the operation are greater in splenic anæmia than in any other disease. In almost all cases adhesions binding the organ especially to the under surface of the diaphragm are present. They may be numerous and exceedingly dense, and their separation may cause a copious and grave hæmorrhage. But they are never so dense nor so strong as to prevent the completion of the operation. The details of the operation in other respects are the same here as elsewhere. At the Mayo clinic up to Sept. 20th, 1920, 73 operations had been performed, with 9 deaths, equal to 12·3 per cent. The after-results are excellent; the rather high operative mortality is due to the technical difficulties of the late cases, which, apart from operation, would all be fatal.

HÆMOLYTIC JAUNDICE.

Two types of disease are recognised: the acquired form of Hayem and the congenital or familial form of Wilson and Minkowski. The former type has been the more fully described, and its clinical history and blood condition more critically examined by Widal. The latter type in respect of its hæmatology was especially studied by Chauffard, who first pointed out that the resistance of the red blood cells to hypotonic salt solutions was greatly diminished. This increased "fragility" constitutes the factor of chief importance in the disease. Of the two, the acquired form (the "Hayem-Widal type") is the more serious, and apart from surgical treatment, appears to be inevitably fatal.

Symptoms.

The symptoms in the two types are very similar—acholuric jaundice, enlargement of the spleen, and anæmia. There is no itching of the skin, and there is not that degree of rapid wasting so often seen in cases of obstruction to the common duct. The blood changes show a reduction in the number of red cells, an increased number of reticulated cells, and a lessened resistance to hypotonic salt solution. In two of the cases of the acquired type which I have seen the symptoms have very closely resembled those of obstruction of the common duct by calculus. In both there were exacerbations of jaundice preceded and accompanied by fever, and by pain and tenderness in the epigastrium. In one of these my diagnosis would certainly have been confidently given as "cholangitis due to calculus," but that a surgeon of great experience had explored the duct and discovered no stone. The diagnosis may be very difficult in cases in which gall-stones also are present. In about 60 per cent. of recorded cases stones have been found in the gall-bladder or in the ducts at the time that operation for removal of the spleen was undertaken.

The distinction between the congenital and acquired forms is real. The congenital form is exceedingly chronic in its duration and quiescent in its manifestations.

The acquired form may begin abruptly and run an eager rapid course from the first. Anæmia quickly becomes profound, the red cells falling to one million within a few weeks. The crises of pain, temperature, and deepened jaundice are more frequent than in the congenital type. In one direction the disease, whether congenital or acquired (generally the latter), may wander away into the neighbourhood of pernicious anæmia. Chauffard describes an "icteric form of pernicious anæmia which, when accompanied by diminished resistance and reticulated red cells, represents the least compensated form of hæmolytic icterus."

Pathogenesis.

The older views that this disease is primarily hepatic in origin are for ever set aside by our surgical experiences; for it is known beyond dispute that removal of the spleen "cures" the patient, who, if the operation has been done in stages earlier than the terminal, remains entirely free from symptoms at all subsequent periods. The spleen, if not the exclusive cause or seat of the disease, exerts the profoundest influence upon its pathogeny.

Several views as to the ultimate causation have been held. Chauffard at first, and Widal later, believed the essential factor to be a dystrophy, an increased fragility of the red cells. This view is held by the great majority of those who have studied the question in recent years. Other authorities, led by Minkowski, hold the opinion that the primary change is an increased hæmolytic activity, probably restricted to the spleen. Widal, the most earnest supporter of the former view, considers that the red cells which are congenitally infirm are destroyed in the general circulation; their remnants are taken up by the spleen, which undergoes enlargement, forming a tumour for which Ponfick introduced the term "spodogenous," and also by the bone marrow, kidney, and liver, all of which are found on post-mortem examination to be deeply pigmented. This opinion has lost ground since the many good results following splenectomy have been witnessed, though, as I shall mention, it does not appear from the very late examination of Sir Spencer Wells's case that the dystrophy of the red cells is always altered even after many years of perfect health following splenectomy. Consequently the altered character of the red cells may be sometimes evidence of faulty manufacture, their lipoid component being deficient, as I have already suggested. This does not nullify the opinion that the spleen has much to say in the subsequent treatment of such defective cells. In my own cases fragility of the red cells disappeared soon after splenectomy, and has not returned. The experience in Spencer Wells's case is, I think, exceptional.

Minkowski's view is held by a few later writers, including Banti, who consider that the spleen is not only enlarged as a consequence of the retention within it of cell remnants, but that within the spleen cells are prepared for destruction and are there actively destroyed. An examination of the spleens removed during life or obtained at autopsy shows no specific change. The deep congestion of the splenic pulp and of the sinusoids, constantly found, is common to many other forms of splenic disease. Occasionally biliary cirrhosis is found at autopsy.

Treatment.

Treatment of this condition is by no means always necessary. The symptoms may be very slight, or may even be absent. If crises occur they may be so infrequent and so speedily pass away that the patient, having suffered from them for years, may pay no serious heed to them. In cases rather more severe, general medical treatment and the use of radium therapy have proved to be valueless. Where the symptoms are troublesome to the patient, and especially so in the acquired form, recourse to operation should be had in as early a stage as possible. It is better not to operate in, or near, a time of crisis, and if the spleen is unduly large its size may be reduced temporarily by the application of radium. Splenectomy has proved to be a specific in this disease. Its dangers are slight; in Kanavel's collection of 48 cases there were 2 deaths; in Mayo's series of 32 cases there was 1 death. And the results are excellent. Within a few days the patient loses the tinge of jaundice entirely, all symptoms disappear, and there is never any recurrence. No operation in surgery gives such swift and striking results. It is very remarkable to witness the change in a patient who has been jaundiced for years or from birth; the skin becomes clear and white, sometimes within 48 hours.

The results at the Mayo clinic up to Sept. 20th, 1920, showed 32 cases with 1 death, a mortality of 3·2 per cent. Like all other statistics of this clinic, they represent the results obtained by a group of men of the highest technical skill, working under conditions unsurpassed elsewhere. They show the level which highly organised surgical endeavours can attain and are an example and an encouragement to all.

CONCLUSION.

It is evident that a consideration of the whole subject of diseases of the spleen must take a very wide view. A number of symptoms may direct attention to the spleen, even when clinical examination does not reveal the presence of splenomegaly. It is through the correct insight into the significance of the clinical symptoms and other morbid phenomena that the real understanding of any supposed case of splenic disease becomes possible. Instead of searching only for the existence of this or that splenic disease, *an inquiry should be directed to the determination of the functional capacity of all the various organs* likely to be deranged. The symptoms already named may be looked upon as evidence of some disorder in the particular *systems* now under consideration. This derangement must be regarded not merely as a restriction of the morbid changes to the spleen, but as a disturbance of wide ramification throughout the whole body, affecting one or other, or perhaps even all, of the four systems in which the spleen plays a part. The focus, at the moment, may in truth be in the pulp of the spleen; but even so, the general picture presented by the patient is the outcome of the participation of the *other systems* in the process which started in the spleen. It may be that splenectomy in any of these diseases will remove the obvious culmination of the morbid process, and thus bring about a "cure" of the disease or an arrest of its development; but it does not by any means follow that all the other related parts are thereby caused to return to their normal states. Absence of symptoms does not imply the restitution of normal functions.

A further step in the investigation of the clinical condition of the patient should aim at the exact discovery of the *site* of the lesion in certain particular cell types: (*a*) in the spleen-pulp; (*b*) in the bone marrow and in any part where reticulo-endothelial cells may exist in specially congregated or active masses; (*c*) in the liver; (*d*) in the endocrine organs, including the pancreas. This lesion being predicted or recognised, the question will arise as to whether it consists in, or entails the elaboration of poisons capable of causing hæmolysis, cirrhosis, or asthenia.

The tissue affected, and the changes therein resulting being recognised, further research must be directed to the discovery of *the type of infective agent* at work, whether bacillary, spirochætal, or other. In other words, the patient is no longer to be regarded merely as the victim of some type of "disease," but as the victim of disorders of a certain character in certain parts of certain anatomical or functional systems of the body. It is the form of the disorder, the form of distribution (determined by an assessment of the functional capacity of the several organs concerned or likely to be concerned), when correctly studied, will inevitably lead to the source and cause of the morbid state, and ultimately to the prospect of the "cure" of the patient.

INOPERABLE UTERINE CARCINOMA TREATED BY THE COLD CAUTERY METHOD OF PERCY.

A SERIES OF FORTY-THREE CASE

BY PERCIVAL P. COLE, M.B., CH.B. BIRM.,
F.R.C.S. ENG.,

SURGEON TO OUT-PATIENTS, CANCER HOSPITAL; SURGEON, SEAMEN'S HOSPITAL, GREENWICH; LATE HUNTERIAN PROFESSOR, ROYAL COLLEGE OF SURGEONS OF ENGLAND.

IN 1914, at the meeting in London of the Congress of American Surgeons, Dr. J. F. Percy demonstrated his cold cautery method at the Cancer Hospital. It fell to my lot to open the abdomen and assist him by palpation the while he manipulated the cautery and explained the various points in technique. Percy's efforts and writings have stimulated discussion, particularly in America, as to the utility of heat as a palliative measure in the treatment of inoperable uterine cancer. Adverse criticism has not been wanting, and controversialists have demanded the production of detailed results. I have operated on 43 cases, and propose to give an unprejudiced account of the difficulties encountered, the dangers, real and fictitious, and the results obtained. I have been assisted throughout by Mr. O. T. Dinnick, whose collaboration has been most valuable. Unvarying assistance in an operation of this kind is an important factor, for experience gained in a succession of cases is the guerdon of operator and assistant alike and can be utilised and applied in a combined and coördinated progress.

Technique of the Operation.

The cautery is heated by electricity, led to it from the main current by way of a converter. The operation itself may be divided, for purpose of description, into (1) abdominal and (2) vaginal.

(1) *Abdominal part of the operation.*—A mid-line incision is made reaching from the umbilicus to pubes. The skin edges are protected and a pelvic retractor of the Doyen type having been inserted into the peritoneal cavity, the intestines are thoroughly packed off with hot moist pads, so that the upper abdomen is completely shut off from the pelvis because manipulations in the pelvis have to be continued over a period ranging from one to two hours. In some cases adhesions of omentum or intestine to the anterior abdominal wall or to the tubes will have to be freed before this procedure can be carried out. Thorough packing also ensures a clear and unobscured view of the pelvic contents. The internal iliac and the ovarian vessels, and the round ligaments are tied off in turn; this part of the operation takes from 10 to 30 minutes. The posture of the patient is then changed from the Trendelenburg to the horizontal position. The abdominal wound is isolated from the perineum by a towel clipped securely across the abdomen below the lower extremity of the incision, and thrown upward to cover the wound and the hand and arm of the assistant engaged in guiding during the next stage of the operation. The patient is then adjusted in the lithotomy position, and the second or vaginal portion of the operation is commenced.

(2) *Vaginal part of the operation.*—In most cases it will be found necessary to dilate the vagina, and this is effected by means of a flange and screw dilator, which is part of the operating outfit. The dilatation is carried to a sufficient degree to admit of the insertion of the water-cooled speculum, also provided with the outfit. This speculum has a surrounding water-jacket space through which water is conducted by means of rubber tubing connected to a raised reservoir and drained away into a bucket placed on the floor at the operator's feet. In this way a constant circulation of cooled water through the water-jacket of the speculum is ensured, and the vaginal walls are thus adequately protected. Several types and sizes of speculum are provided with the outfit and selection is made according to the size of the vagina, the situation and extent of the growth, and the particular area of the growth to be dealt with. Through this speculum a clear view can be obtained of the cervix and the vaginal vault, and decision can be made as to whether or not a curette may usefully be employed to remove the redundant growth. The position and direction of the uterine cavity is then determined by the passage of the uterine sound, and the position and relation of the bladder to the involved cervix is similarly ascertained. The manipulation of the cautery is then commenced. The assistant, with his hand in the abdomen, from

this time onwards grasps the fundus of the uterus and controls the position and direction of the cautery point, either by verbal directions to the manipulating operator or by movements destined to bring palpable growth in contact with the heating agent. As a rule, the cautery is passed through the cervical canal until its tip can be felt at the top of the fundus by the hand of the abdominal assistant. In this situation a thorough heating of the cervix and fundus is carried out. The ordinary cooking degree of heat may be roughly estimated by trying the cautery upon a piece of wood. The heat adjusted by means of a rheostat should be just insufficient to char the wood. When the cautery is in position and in contact with the tissues, a gentle sizzling sound can just be heard by the cautery operator. The estimation of adequate heating rests with the abdominal assistant. The part in process of treatment may be pronounced by him as adequately heated when the heat transmitted from the cautery through the intervening tissues to his gloved hand is such as to be just bearable. When fundus and cervix have thus been dealt with, the abdominal assistant directs the cautery towards outlying areas in the bases of the broad ligaments. The lower portion of the cervix and involved areas in the vaginal vault must be dealt with by the cautery operator, who has these parts under his direct survey, and it is particularly in these manipulations that care and discrimination must be exercised. Although a much greater degree of heat may well be utilised in forcing the passage of the cervix and destroying growth on a thickened posterior lip, no such heating can be tolerated in dealing with the anterior aspect of the cervix and the anterior vaginal fornix. For dealing with this particular area Percy has devised a speculum interrupted for about one-sixth of its circumference. He suggests that the interruption be made to coincide with the danger area lying anteriorly, and the necessary degree of heat may be obtained therein without direct contact with the cautery, the degree of heat being estimated by means of a thermometer passed through the urethra and resting in the bladder. The changes which occur in the heated parts are characteristic. The fundus becomes soft, tumid, and juicy, so that at the end of the cauterisation a varying quantity of slightly blood-stained fluid has accumulated at the bottom of the pelvis. In addition, the pelvic organs, which at the commencement of the operation had exhibited a more or less intensive degree of rigidity, exhibit a softness and mobility which is both unexpected and characteristic. The appearance of the treated area looked at from below is also characteristic. The cervix presents a large funnel-shaped crater, the sides of which are quite firm and perfectly dry and of a peculiar greyish-yellow colour.

This part of the operation being completed, the patient is released from the lithotomy position, all towels except those clipped to the skin edges are changed, and the abdominal wall sewn up in three layers by the assistant.

In 1914 the intra-abdominal portion of the procedure was confined to directing the position of the cautery by palpation. The first few cases showed clearly enough that severe secondary hæmorrhage was a danger to be anticipated. As a preventive measure it was decided to tie both internal iliac arteries, the ovarian vessels, and the round ligaments. In every subsequent case this has been done, and as a result no further instance of secondary hæmorrhage has occurred. It is interesting to note that Percy himself was compelled to adopt a similar procedure for the same reason.

Certain Difficulties.

The ligature of the internal iliacs may be very easy or very difficult. In many cases the tubes are bound down at the back of the uterus to the peritoneum covering the pelvic floor, to the pelvic colon, or to the mesocolon itself. Apart from any adhesions affecting the adnexæ, the pelvic colon with its mesocolon has often contracted adhesions or adventitious peritoneal attachments to the posterior and lateral pelvic walls. When tubes and ovaries are bound down in the manner thus indicated it is essential that they be thoroughly freed, and in this case their removal is indicated. Adventitious attachments of the colon must also be freely severed to allow free access to the outer aspect of the pelvic meso-colon to permit exposure and ligature of the left internal iliac artery. The pelvic viscera being thus freed the ligature of the iliacs is proceeded with. In a case presenting any or all of the inflammatory adhesions above described ligation of these vessels is almost certain to be difficult. These difficulties, however, are dependent on such anatomical factors as the depth and conformation of the pelvis and the thickness of the abdominal wall, for it must be remembered that a considerable amount of superficial fat is often enough encountered in operating upon patients in whom cancer of the cervix has developed to such an extent as to render the condition radically inoperable.

Danger to the ureters is practically negligible, for these structures, lying as they do immediately in front of the iliac vessels, must inevitably be exposed before the vessels can be reached. Occasionally, however, it happens that the vessels lie embedded in dense tissues, the nature of which, inflammatory or malignant, is impossible to determine. Even in such a case the danger of wounding the internal iliac vein is much greater than that of causing damage to the ureter. In an ordinary case, the iliac vein separates readily from the posterior aspect of the accompanying artery, and reasonable care only is necessary to avoid damaging it. In a case such as that predicated separation is difficult and the walls of the vein, stiffened by the surrounding tissue, may well be perforated unless the greatest care is exercised. Such an accident occurred on one occasion in this series and a fatal result ensued.

On one or two occasions adhesions of omentum to abdominal wall and pelvic viscera, and dense matting of the viscera themselves have been so extensive as to preclude a definition of the pelvic cavity, and in such a case operation must necessarily be abandoned, for it is not, I think, justifiable to proceed with the cauterisation per vaginam without control exercised from within the abdomen. The vaginal portion of the operation may be immediately complicated by inability to define the position of the cervical canal. In such a case a passage must be forced by the cautery heated to a relatively high temperature, and guided in its course by the orientating hand of the abdominal assistant. Often the posterior vaginal wall in the region of the fornix and the posterior wall of the cervix are so destroyed by growth that they consist of little more than peritoneum. Perforations in these situations by curette or cautery are not uncommon, but owing to the relation of the recto-vaginal pouch of peritoneum the rectum itself is in little danger, and, in fact, has never been injured. The anterior aspect of the cervix and the anterior vaginal vault are not so happily situated. The close relationship of the bladder must be constantly borne in mind, for the one great immediate drawback to the operation is the development of a vesico-vaginal fistula. The area of bladder thus liable to be involved is that extending from the level of the internal os above to within three-quarters of an inch of the urethral orifice below.

Mention has been made of the interrupted speculum devised to deal with growth in this region. I have, however, found this of little practical utility. A factor of greater importance is the size and shape of the active end of the cautery. The end usually employed has far too pronounced a shoulder at its junction with the handle-shaft, and I feel sure that a modification of the instrument along the lines indicated would prove more efficacious in preventing the formation of these distressing fistulæ than the use of the interrupted speculum. No instance of a uretero-vaginal fistula has occurred in this series, and this is somewhat extraordinary in view of the thorough heating to which the bases of the broad ligaments have been subjected and compares favourably in this respect with the Wertheim operation. No recto-vaginal fistula has been caused by the use of the cautery, but in a case operated on in January, 1920, a small recto-vaginal fistula followed the embedding of radium needles into the remnants of the posterior cervical wall. Secondary hæmorrhage, as has previously been mentioned, is a formidable complication unless the internal iliacs are ligatured. This being done, bleeding at the time of operation is very slight, and the hæmorrhage as an immediate consequence of the operation is almost unknown. In one case the separation of a large slough was accompanied by a smart outburst of bleeding, but this was not repeated, and the patient made an uninterrupted recovery.

As a preliminary to the application of heat, allusion has been made to the use of the curette as a means of removing redundant growth. This procedure was found to be considerably facilitated by the pelvic ligation of vessels, for oozing was reduced to a minimum, and a clear view obtained without the necessity for constant swabbing. This use of the curette is denounced by Percy,[2] but I am satisfied that it saves time, and cannot conceivably do any harm. Two grades of heat have been utilised—a high grade that destroys, and a lower grade that cooks. Percy originally was opposed to destructive heat, but he admitted that this may be of value in certain positions and under careful control. In forcing the passage of the cervix, and destroying superficial growth, the use of destructive heat is undoubtedly indicated, the heat-blocking effect of the eschar being obviated by the removal of as much burnt tissue as possible. This can readily be effected with a pair of stout sponge-holding forceps. In the great majority of cases the forcing of the cervical canal has demonstrated the existence of a condition of pyometra. The appearance of many of these patients was impressively indicative of toxic absorption, and the extraordinary improvement in their complexion and facial aspect within two or three days after operation can best be accounted for on the assumption that pyometra was the causative factor. The duration of the operation has varied from one to two hours.

The Type of Case.

Gauged by whatever standard the type of case subjected to operation was, from the radical point of view, inoperable. The cases were drawn from the chronic wards at the Cancer Hospital. The patients in these wards are recruited from inoperable cases so certified by practitioners or admitted as such from the out-patient department, and in every case their condition is verified by the visiting staff. By far the greater number in this series had been seen and rejected as inoperable by gynæcologists of repute at large London and provincial hospitals. The intra-abdominal condition obtaining in these late cases presented many points of interest. Matting and adhesions have already been mentioned. The rarity of demonstrable glandular invasion was remarkable. Comparative figures support the view that this freedom from glandular metastases was not only apparent, but real. Leitch,[15] in a series of 915 post-mortem examinations, found glandular invasion in 351, or 38·36 per cent. The number in which metastases of any kind occurred was 405, or 45 per cent.; in other words, 55 per cent. of cases which run their course without surgical intervention die as a result of effects determined by what remains to the last a local lesion.

These figures are confirmed by the notes of a series of 100 post-mortem examinations undertaken at the Cancer Hospital. Twenty-four cases had glandular deposits and 9 had visceral deposits, giving a total of cases with metastases of 39 per cent.; this percentage is lower than that recorded by Leitch, but the number concerned is smaller, and includes 5 cases which had been subjected to radical operation. Dilated ureters on one or both sides were commonly met with. Occasionally this dilation would be extreme, the ureter approximating in diameter to that of the little finger. It is interesting to note that Leitch in his series of 915 found the kidneys hydronephrotic and the ureters dilated in 75 per cent. of the cases.

No selection was exercised in the choice of cases in so far as concerned the local condition. Attention was directed to the general condition only, no case being dealt with unless this was sufficiently good to render reasonable the immediate risk incurred. Experience has shown that local conditions should be considered, and this aspect of the question will be referred to in discussing post-operative sequelæ. One case—not included in the series—was treated for recurrence in the vaginal vault, following a radical panhysterectomy. She suffered from oft-repeated hæmorrhage and died in a few weeks. The unsuitability of cases recurrent after radical operation had been confirmed by Percy.[6]

Post-operative Progress and Sequelæ.

The abdominal wall in every case has healed without a trace of suppuration. Allusion has already been made to the striking improvement in general aspect that occurs within two or three days of operation. Slight reactionary temperature may persist for the first few days. It has caused no more anxiety than that which frequently obtains after a supravaginal hysterectomy. Shock has never been encountered. This is the more noteworthy in view of the age of some of the patients. Several were over 50, and one was 68. These findings are at variance with those of Bancroft, who lays stress on shock and temperature as inimical factors.[7,8] In three cases sloughs of considerable size have been passed per vaginam, and in one case the coincident loss of blood was considerable, but was not repeated. A foul discharge may commence on the third or fourth day, and persist about a fortnight. It is advisable to administer a weak iodine douche beginning on the fourth day, and continued till discharge ceases. Patients are kept in bed for three weeks and leave hospital at the end of a month.

Vesico-vaginal fistula has resulted in seven cases. This is an uncomfortable and intractable complication. The leakage may diminish somewhat, but healing never takes place. In one case (No. 26) an attempt has recently been made to remedy the defect by converting the vagina into an annexe of the bladder. The fistula, however, was so close to the urethral orifice that control has not been established. One patient (No. 36) is dry while lying in bed at night, but constantly leaks during the day. It is particularly with regard to this unhappy occurrence that careful selection should be exercised in the choice of case. In considering the question of fistula formation it must not be forgotten that the condition must inevitably arise in a large number of cases as a direct result of the disease. Thus, Leitch, in his series of 915 end-results of inoperable cases, records 44·2 per cent. of vesico-vaginal and 16·5 per cent. of recto-vaginal fistulæ.

(l) = living.

Consideration of Results Obtained.

The best estimate of the results will be obtained by considering separately the categories indicated in Table II. The first group—those not discharged from hospital—includes four cases who died within a month after operation, and this may be regarded as the primary mortality. The other four cases, although living for periods of from two to ten months, were confessedly failures in so far that no claim is made that any definite benefit was conferred upon them. The second group deals with four cases who were re-admitted and died in hospital. These were Nos. 7, 13, 22, and 27. The cause of death was as follows:—

Case 7 was seen as an out-patient six months after operation. She had then no discharge or pain, and had gained weight and strength. She was readmitted one month before she died on account of occasional hæmorrhage noticed for two months previously. Radium was embedded, followed by hæmorrhage, and she died of uræmia. This patient had two years of life free from symptoms and enjoyed throughout that time good health.

Case 13 was an utter failure. She was admitted for colostomy, and died as a result of the operation.

Case 22 was readmitted after three years for radium implantation, recurrence having given rise to some blood-stained discharge. Before any treatment was carried out she developed intestinal obstruction, from which she died.

Case 27 was quite well until immediately before readmission. She was admitted for hæmorrhage and died therefrom three weeks after.

The average life duration in this group is 20 months, and three of the patients were undoubtedly benefited to a very considerable degree. The third group include those cases who were discharged from hospital, were never readmitted, but died outside the institution. For the after-history of these cases one has been dependent upon the out-patient notes and answers to inquiries made by post. Out-patient notes on many of the cases are not existent owing to the fact that so many of these cases have been admitted from places situated a long distance from the hospital, a factor which has precluded their further attendance. The answer to inquiries have been disappointing, largely owing to the lack of education among the patients and their friends. In many cases nothing more than the date of death was indicated.

Notes on Certain Cases.

A few notes obtained on some cases may serve to indicate the relief, or otherwise, afforded. These notes have been culled from the sources above indicated, and are set forth without selection.

CASE 1.—Seen as out-patient eight months after operation. Uterus freely movable, slight bleeding on examination, no ulceration, some right-sided pain, diagnosed elsewhere as appendicitis. Cause of death unknown.

CASE 6.—Seen five months after operation. No discharge, no hæmorrhage, some pain radiating down the left leg. Died 16 months after operation. Cause of death unknown.

CASE 10.—Was discharged from hospital free from symptoms—no discharge, no hæmorrhage—greatly improved in health. Died 15 months after operation. Cause of death unknown.

CASE 18.—Seen three months after operation and noted as an excellent result in every way. Eight months after operation small local recurrence noted. Attended out-patients to within two months of her death, which was determined by hæmorrhage two years after operation.

CASE 23.—Seen seven months after operation and stated "that she never felt so well." Ten months after operation began to lose weight. This was shortly followed by polyuria. Died 14 months after operation from hæmorrhage.

CASE 32.—Seen two months after operation and noted as being better in every way. Seen again six months after operation, when there was no sign of malignancy locally, but it was noted that she had free fluid in the abdomen. This patient died 15 months after operation from diffuse malignant peritoneal invasion.

CASE 40.—Lived only five months, and although free from symptoms never recovered her health. No definite cause of death is known.

CASE 41.—Lived only three months. No definite cause of death known, but was free from discharge, hæmorrhage, and pain.

The average duration of life in this group was 16 months. All patients discharged were immediately relieved of all symptoms, and, basing our deductions upon known histories, it would appear that death usually ensues very soon after the onset of any symptom indicating renewed growth.

Leitch gives 21 months as the average duration of life from the commencement of the disease, as determined by the date of the exhibition of the first symptom. Every case in my own series had been pronounced inoperable, and in many cases application for admission was not made until the lack of facilities at home forced the patients to seek institutional aid. Again, varying periods necessarily elapse between application and actual admission. In view of these considerations, it is not, I think, unfair to estimate that the average expectation of life could not have exceeded six months.

A better idea of the economic value of the increased term of life thus conferred may perhaps be gathered from a consideration of the cases—seven in number—still living. These are Cases 25, 28, 30, 35, 36, 42, and 43. Of these, Case 43 has been operated on only two months and may be excluded from consideration. To take these cases separately:—

CASE 25.—This patient, seen on Nov. 24th, 1920, was in perfect health. She is able to live a normal life and to do quite as much as any normal person of her years. She has a vesico-vaginal fistula and is compelled to wear a urinal, but she has no discharge, hæmorrhage, or pain, and shows no sign of any malignancy.

CASE 28.—For two years this patient was absolutely free from any symptom associated with malignant disease of the cervix. She was normal in every way and in perfect health. Since then she has had several severe hæmorrhages and has been treated consistently with X rays. Between her admissions to the hospital she gets about, but her life for the last few months cannot be regarded as of economic utility.

CASE 30.—I saw this patient on Nov. 24th, 1920. She lives in Bedfordshire and walked five miles to the railway station. She has a husband and two children, the youngest being 4 years old. Her husband has been receiving a pension of only 25s. a week, and she has been enabled to go to work and be largely instrumental in keeping the family. She was only 32 when subjected to operation. She looked and is well and strong, and exhibited no indication of malignant disease. This is the most strikingly successful case in the series.

CASE 35.—This patient has a vesico-vaginal fistula and wears a urinal. She was admitted to hospital again in November, 1920. The closure of the fistula was impracticable, due to small recurrence close to its margin. Three radium needles were embedded. She had no discharge, no hæmorrhage, and no pain, and both looked and felt well. This case was at the time of operation noted as being particularly unsuitable.

CASE 36.—This patient, although free from discharge and hæmorrhage, has been a more or less chronic invalid. She was admitted in August, 1920, for radium embedding, but refused treatment. The operation was performed 15 months ago.

CASE 42.—I saw this patient on Nov. 24th, 1920. She was then in splendid health and showed no evidence of malignant disease. This case was remarkable in that in addition to the primary growth at the cervix she had a large secondary mass at the vaginal outlet. This was removed with a knife and the area freely treated by diathermy. The mass was submitted to the pathologist, who reported it to be a secondary epithelioma. The first operation was undertaken in January, 1920.

Remarks.

The penetrating power of the low heat advocated by Percy and the alleged vulnerability of cancer cells to a degree of heat insufficient to destroy the vitality of normal tissue cells are questions which existing data do not suffice to decide. Boldt[9] relates the result of a post-mortem on one case soon after operation, and concludes that Percy's contentions are thereby refuted. It is, however, not intended to institute a comparison between the cautery method and the radical panhysterectomy. It is frankly recognised that the operation is palliative and should be reserved for advanced cases, or for cases in which radical operation is deemed unsuitable. To this extent, then, it may be fairly regarded as a rival to treatment by radium. It is not my purpose or desire to institute such comparison, for of late I have learned to regard them not as rivals, but as partners. It must be frankly confessed that a number of cases in this series have failed, and that failures must be expected in a proportion of cases varying with the amount of selection exhibited. It must be remembered, however, that the condition of the patients in this series could with difficulty be made worse, and that to that extent any relief obtained is to the good. Bearing these facts in mind, and with determination to combat discouragement, it might, I think, fairly be taken that this operation, particularly when reinforced by consequent radium treatment, should have a place in the armamentarium of a surgeon who would endeavour to undertake the treatment of inoperable cancer. With the cautery and radium together, used discreetly and discriminately, a great deal may be done, perhaps more than has been done, to alleviate the distressing disabilities of inoperable uterine cancer, and in many cases to restore to those suffering derelicts peace of mind, together with the chance of an increased term of economically useful life.

ANXIETY PSYCHONEUROSIS.

BY ALFRED CARVER, M.D., D.P.M. CAMB.

(From the Birmingham Clinic for Functional Nervous Disorders.)

THE English language contains no single word which exactly expresses the meaning of the German "Angst" or the French "angoisse." The word "anguish" is generally too strong, while "anxiety," as commonly used, is far too weak—e.g., anxiety to catch the post or a certain train is expressed in everyday speech. The latter term requires qualification when applied to that type of anxiety experienced and manifested by the psychoneurotic. Were mental factors alone under consideration the term "morbid anxiety"[1] would be appropriate, but as the physical concomitants of this mental state must also be taken into account some term which includes them is desirable. This has been sought by such designations of the total symptom-complex as anxiety neurosis, anxiety hysteria, anxiety state, or, more rarely, anxiety psychoneurosis. The first two of these terms unfortunately stress a subsidiary hypothesis rather than the essential morbid anxiety. The term anxiety neurosis was introduced by Freud to describe a group of cases in which the symptomatology was considered to depend upon an actual physical tension. Since its introduction the term has been loosely and ignorantly used. Freud, of course, did not imagine that all morbid anxiety was thus determined; indeed, in a paper on "wild psycho-analysis," he states explicitly that "he who suffers from morbid anxiety is not necessarily the subject of an anxiety neurosis." Further study has shown that in all cases of morbid anxiety, even where a physical origin might be assumed, the mental factor always coexists and is the more important of the two. The term anxiety hysteria signifies that the mental mechanism concerned in the production of the symptoms is similar to that operative in other forms of hysteria. Unfortunately there is no general agreement as to what constitutes hysteria, and many different definitions are current at the present day.

Morbid Anxiety.

The term psychoneurosis does not labour under such great disadvantages, and if it be confined, as it should be, to functional nervous disorders with predominantly mental symptoms due to emotional disturbances the designation anxiety psychoneurosis would be most appropriate to that group of cases the main symptom of which is morbid anxiety with its physical concomitants. Defined in this way, anxiety psychoneurosis is the commonest of the many neurotic disturbances which have arisen out of the war, yet it has not received the amount of attention which its importance warrants. This is probably due to the fact that the more showy somatic dissociations, which, following Freud's nomenclature, are now termed conversion hysterias, absorb the attention of a majority of workers in this field of medicine. Upon closer study, however, morbid anxiety is found to be the primary mental disorder upon which the other psychoneuroses are built as superstructures, most of the superimposed symptoms being produced as the result of an effort to defend the Ego from the baneful effects of morbid anxiety.

At the present time few cases of conversion hysteria are met with among pensioners, while a high proportion of those coming before the neurological boards and clinics is found to be suffering from morbid anxiety alone. The reason for this need not now detain us, but if the view that in the psychoneuroses morbid anxiety is the primary mental disturbance be granted, one would expect to meet it uncomplicated in many early and slight cases, and as a corollary of this the removal of any superimposed protective symptoms which had temporarily masked morbid anxiety would, unless further and more radical treatment were employed, allow it again to become manifest. Experience shows that this is unfortunately of frequent occurrence, especially with conversion hysterias.

Symptoms of Morbid Anxiety.

Before entering into the psychopathology of morbid anxiety, it will be well briefly to survey the symptoms as exhibited by a moderately severe case. There is the typical anxious facies, the startled and strained expression with widening of the palpebral fissure and dilatation of the pupils; the speech, even if not definitely stammering, is characteristic; tremor and hyperhidrosis are almost invariably present. Respiration is shallow but hurried; there is tachycardia, experienced subjectively as palpitation or jumping of the heart. Often a sinking or fluttering sensation in the epigastrium is complained of and may be associated with diarrhœa and frequency of micturition. All the above symptoms indicate an overactivity of the vegetative nervous system and are recognisable as the physical concomitants of the emotion of fear. Yet as a rule the patient does not lay stress upon any of these symptoms nor, unless definite phobiæ have developed, does he realise that he is in any way suffering from fear. He complains rather of being easily upset, of headache, irritability, inability to concentrate, and easy fatigability; of bad dreams, and lack of sleep. It is this group of symptoms and not those previously enumerated which render him unable efficiently to carry out his daily work. Being easily upset is, in the absence of a definite phobia, always the cardinal symptom.

Use of Psycho-analysis.

As physical examination leads us no farther we must proceed by some method of mental exploration to inquire into the psychopathology underlying the production of the symptoms. Suppose we adopt analysis. The analyst asks the patient to relate freely everything he can about himself. The patient generally starts off well pleased, for there is nothing that the neurotic likes better than a sympathetic audience; but in this case he has reckoned without his host. Very soon the alert analyst notices hesitation, pauses and hiatuses in the story, or that his patient is getting uneasy, perhaps even showing an increase of tremor or sweating. The analyst, who has hitherto been passive though very much on the qui vive to detect such signs or any of the subterfuges by which they may be masked, now urges the patient and keeps him to the task, never allowing him to slur over or treat impersonally any subject which is coming up in his mind. The analyst must urge and encourage the patient, and must interpret to him the significance of any method of evasion which is either consciously or unconsciously employed, but in so doing must scrupulously avoid making any suggestions to him. By this means the patient is gradually brought to unfold his personality and the resistances are broken down. It has been found more advantageous to proceed by this method than to attempt a direct attack upon the symptoms while the resistances are still in force. The need for overcoming the resistances and bringing out the dissociated and repressed experiences in their minutest detail is exemplified by the following case:—

A soldier, in the R.F.C. at the outbreak of war, developed in 1917 an anxiety psychoneurosis after crashing near his aerodrome in France. He described the actual crash without much difficulty, but although he

---

[1] The morbidity of the anxiety consists in its being out of proportion to the apparently exciting cause.

had been conscious after the fall he showed an amnesia from that time until he found himself in the aerodrome again. This might easily have escaped notice, yet it contained an important clue to the cause of his morbid anxiety. Great pressure was needed before he could fill in that gap, but eventually the following story came to light. As he was being carried to the aerodrome he had to pass a spot where a great friend of his had previously crashed with fatal results. A rescue party, which included the patient, had set out on that occasion, but as they neared the spot the bombs on the crashed and now flaming aeroplane had detonated, killing several of the party.

The intolerable idea from the recollection of which he shrank was thus not his own crash. One might have been satisfied that in uncovering the second experience, which recalled the death of his friend, one had reached the root of his trouble. But the full story was not yet told; it appeared later that when the bombs on the burning aeroplane had detonated and killed some of the would-be rescuers, one of the party, mortally wounded, was hurled against the patient, knocking him down and falling on top of him. Lying upon the patient, this man died, a convulsive tremor shaking his body. It was the idea of this experience, seeking to return to his mind as he passed the spot, which was to the patient so intolerable that he "forgot" all about it. It is this "forgetting" of experiences with an unbearable affective tone which Freud has termed repression, and repression is the very foundation-stone of Freudian psychology and of psycho-analysis.

Repression: Substitution.

The development of symptoms is not an immediate result of repression, but is due to what Freud terms the return of the repressed material, which can take place only when certain conditions are fulfilled. The aim of repression is to keep from consciousness the unpleasant affective element of an experience. With this intent the whole experience is repressed. So long as it can be fully maintained the repression may be described as successful, but if only the ideational element of the complex is excluded from consciousness, while its affective element disturbs consciousness in the form of morbid anxiety or other symptoms there is a partial failure of repression. The anxiety properly appertaining to the dissociated idea now manifests itself in connexion with a suitably associated idea. That is to say, another idea is substituted for the repressed one, and the disagreeable effect is displaced on to the former. Displacement continues to spread, for it does not matter what is feared so long as it is something other than the original excitant of the emotion. Thus in course of time almost any disagreeable stimulus becomes capable of stimulating the complex through substitution, and so of affording an outlet to its affective element. This accounts for what was emphasised as the cardinal symptom in morbid anxiety—viz., "being easily upset." If a suitable symbolic idea is substituted for the ideational element of the complex a phobia for the object of this idea is developed. Morbid anxiety may then arise, either through the spontaneous activity of the complex, or through its stimulation, symbolically, by the object for which a phobia has developed.

For effective treatment of the condition the repressed idea which is symbolised by the object must be brought to consciousness. No amount of common-sense reassurance is adequate to free the patient from his phobia, which, indeed, he himself recognises as irrational. When, however, he can be brought to overcome the resistances determining the repression which motivated the development of his phobia the latter soon loses its morbid power over him. The soldier of whose history a fragment has already been given had a phobia for long narrow passages. Naturally he avoided such places, but if ever he did attempt to force himself to go into one a condition of panic ensued. We see, then, that the phobia is in a sense protective, its function being to keep the patient away from situations or objects which by stimulating his repressed complex produce in him a state of acute morbid anxiety or panic. Superficial analysis of the phobia of long narrow passages showed it to be connected, via the incidents already recorded, with repressed experiences which had occurred in some caves on the retreat from Mons, although, be it remembered, the patient had been a fit flying man during three years after these experiences. Great resistance was encountered in overcoming this repression, which finally was only cleared up by the aid of analysis of a recurrent dream. Into this there is no need to go; it is sufficient to indicate, in passing, the great help which in such cases may be derived from dream-analysis. A legitimate question which obtrudes itself here is as to whether a superficial analysis such as that fragmentarily reported above—which, nevertheless, sufficed to remove the patient's symptoms—is all that ought to be attempted. Can it be said that the patient is cured when his symptoms have been removed in this way? Is not the condition upon which they were enabled to develop left untouched? From the practical point of view we must generally rest satisfied when the symptoms have been relieved; yet during the course of an analysis even so superficial as that recorded above, glimpses are caught of deeper-lying repressed material, and we are compelled to inquire whether the repressions of later life can come about de novo in an individual whose previous development has proceeded harmoniously. Freud, by tracing the psychic ontogeny both of neurotic and of apparently normal[2] individuals, has answered this question in a very emphatic manner; though, needless to say, his answer has not met with anything like general accord. As a result of his studies Freud has come to the conclusion that "the repressions of later life are only possible in regard to the derivatives or other connexions of the primordial repressions which take place in infancy." Had Freud stopped here it is possible that few would have contradicted him, but after going on to show that morbid fear is only the obverse aspect of desire, he argued that in ultimate analysis all desire is "sexual" in origin. (It must be borne in mind that Freud's conception of sexuality is much wider than the current connotation of the word, so that even the admissibility of the term "infantile sexuality" has been hotly disputed.) The individual's primitive "sexual" wishes undergo repression in the course of his development, because they are repugnant to the standards of his later developing ego-ideal. According to Freud, it is upon this primordial basis alone that the repressions of later life are buildable and are built. In any case it is always a failure of adaptation to existing circumstances which leads to regression, and thus revives former modes of reaction. The later events, which are commonly regarded as causal, only play the rôle of favouring, through regression, a return of the repressed material.

Conclusion.

What the subject of morbid anxiety really fears is, therefore, in ultimate analysis his own primitive desires, or, more tersely, a part of himself. In conclusion, I would add that, so far as my experience goes, it is rarely necessary in the true war anxiety psychoneuroses, where the factors determining regression are quite unusually severe,[3] that mental exploration should proceed so far as the deepest levels; but in some of them, as in most civilian cases, it is therapeutically needful as well as scientifically interesting to reach the level of the primordial repressions.

---

[2] The normal individual is only a scientific abstraction.

[3] In war cases, as I have previously pointed out (THE LANCET, 1919, ii., p. 193) dissociation may occur as the result of a sudden physical shock without prior morbid anxiety. Subsequently, however, if he tries to repress the recall of this disagreeable experience symptoms of morbid anxiety develop.

SCHOOL CLINIC AT POOLE (DORSET).—A new school clinic has recently been opened at Poole, the mayor officiating at the ceremony at which many of the local teachers were present. The clinic consists of dental and refraction rooms, waiting- and bath-rooms, and a well-lighted and well-equipped laboratory. The attendance of mothers seeking advice as to young infants is encouraged, in the hope of linking up infant welfare and school work as a means towards establishing a public health conscience among the people.

DISSECTION OF THE FAUCIAL TONSILS UNDER LOCAL ANÆSTHESIA.

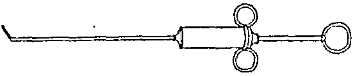
BY W. MORRIS, F.R.C.S. EDIN.,
AURAL REGISTRAR TO THE LONDON HOSPITAL.

THE purpose of this communication is to describe briefly the technique adopted in the Mayo Clinic for the complete removal of the tonsils in adults. I am tempted to write it without apology, because the technique should appeal—by its very simplicity and the ease with which it is carried out—to those surgeons who, like myself, have experienced difficulty in arresting post-operative hæmorrhage, and even in removing the type of tonsil which I shall describe below. I found, during a recent visit to the Mayo Clinic, that dissection under local anæsthetic was the invariable method of removing tonsils in all adult cases. While the results obtained were naturally excellent I consider it a waste of time to adopt this method in cases where there is sufficient tonsillar tissue to be protruded through the ring of a guillotine and dislocated forwards in front of the alveolar process, as in Sluder's method. It is, in my opinion, pre-eminently suitable for small fibrotic tonsils, or those in which the bases only are left, after attempted enucleation by Sluder's method has been performed by an inexperienced operator.

The following instruments[1] are used:—

(*a*) All-metal syringe with a long shank. Total length 8 in. Needle ¾ in. long at an angle of 45° to the shank. Barrel of syringe to hold 1 drachm. (Fig. 1.)

FIG. 1.



(*b*) Tonsil forceps (vulsellum type) 8 in. long, blades ¾ in. long, curved at an angle of 45° to the shank, and jaws opening laterally. (Fig. 2.)

FIG. 2.

(*c*) Scissors 8 in. long, blades ¾ in. long, curved on the flat to an angle of 45°. Points medium blunt. (Fig. 3.)

FIG. 3.

(*d*) Dissector 8 in. long, flat, blunt-pointed blade ¾ in. long, curved on the flat to 45°, both edges being sharp. (Fig. 4.)

FIG. 4.

(*e*) Tonsil clamp. As scissors. Crushing surface ⅛ in. broad.

(*f*) Artery forceps. As scissors. Fine-pointed.

(*g*) Pillar retractor. (Fig. 5.)

FIG. 5.

(*h*) Coarse wire snare.

Anæsthetic. (To be injected at points shown in Fig. 6).—Adrenalin (1/1000), ♏1; cocaine hyd. sol. (0·2 per cent.), ad drachm 1.

Position of patient.—Sitting up in a high chair with a head support.

Operation.—The tonsil is firmly grasped by the vulsellum forceps and pulled towards the middle line. The capsule is then cut with the scissors in the supra-tonsillar fossa. The blunt point of the dissector is introduced into the opening thus made, and the tonsil separated from the anterior and posterior pillars by cutting the mucous membrane in a downward direction in front and behind the tonsil. This can equally well be done with the scissors by inserting the closed points into the opening already made in the supra-tonsillar fossa, and opening the blades in front of and behind the tonsil.

With the scissors the tonsil is then separated from its bed by small nibbling cuts, starting at the upper pole and working downwards for about two-thirds of the extent of the bed.

FIG. 6.

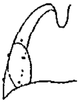


FIG. 7.

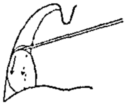

FIG. 8.

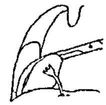

FIG. 7.—Separation of the anterior and posterior pillars with dissector.

FIG. 8.—Tonsil clamp applied to lower third of base of tonsil.

The tonsil is next pulled well towards the mid-line, and the tonsil clamp applied to the remaining undetached portion of the base of the tonsil. Removal of the tonsil is completed by passing a coarse wire snare over the vulsellum forceps, cutting through the remaining portion of the bed, and removing the clamp.

Some operators state that the use of the clamp is not advisable, as it occasionally gives rise to delayed hæmorrhage; they prefer to use the snare alone and ligature any bleeding points afterwards. The whole of the tonsillar fossa can now be exposed by pulling the anterior pillar forwards and outwards with the pillar retractor, and any bleeding points can be secured and ligatured. In expert hands the removal of each tonsil takes about two minutes.

After-treatment.—A plain mouth-wash three times a day and a mild laxative.

Diet.—Ice-cream for two days; then milk, custard, &c., until the patient can bear to swallow more solid food. Most of the patients were on full diet in six days.

In 72 cases witnessed during my stay I saw no ill-effects from the injection of cocaine. The bleeding during the operation is negligible, and a clear view of the operation field is always obtainable. No case is allowed to leave the theatre until the operator is certain that the bed of the tonsil is dry. The patients state that the operation is without pain.

I consider this to be the ideal operation for complete removal of the tonsils in those cases for which Sluder's method is impracticable for the reasons stated above. In the Mayo Clinic it is used for all adult cases; in my opinion this is unnecessary, as the majority of the cases could be completely enucleated with the guillotine. The operation is practically bloodless, and a clear view of the field is obtainable. All bleeding points are ligatured at once, and the risk of secondary hæmorrhage reduced to a minimum. The use of local anæsthesia gives the operator much more freedom and facilities than does the use of general anæsthesia.

A STUDY OF THE
INDICATIONS FOR REMOVING TONSILS
BY DISSECTION OR BY REVERSE GUILLOTINE.

BY MICHAEL VLASTO, M.B.LOND., F.R.C.S.ENG.,
AURAL SURGEON, QUEEN'S HOSPITAL FOR CHILDREN; ASSISTANT IN EAR, NOSE, AND THROAT DEPARTMENT, CHARING CROSS HOSPITAL.

IN some cases, tonsillotomy—the removal of a portion of the tonsil—either by removing the superficially infected crypts or by securing drainage for the deeper ones, may relieve the patient of the symptoms for which the operation was indicated, but to-day it is universally accepted that the only operation that can be entirely relied upon to achieve this result is that in which the whole of the tonsil is removed together with its capsule. This is enucleation of the tonsil, or tonsillectomy.

It is necessary for the purpose of this paper to recognise two classes of operation—viz., those performed on (1) children, and (2) adults.

Enucleation of the Tonsil in Children.

The conclusions arrived at are based on a series of over 1500 cases. Prior to G. E. Waugh's publication in

---

[1] These are being made for me by Messrs. Mayer and Phelps, of 59, New Cavendish-street, London, W.1.

THE LANCET of 1909,[1] it may be stated that in a general way *tonsils were removed by the now antiquated* guillotine method with which we are all familiar. The advantages claimed by him for his operation over that of the guillotine, as then practised, were so obvious that he immediately secured a crowd of disciples anxious to practise the technique that he had elaborated and preached.

Advantages of Enucleation by Dissection.

First and foremost he claimed that enucleation of the tonsil *by dissection* was the only known method for complete removal of the tonsil; his statement reads as follows: "Even in highly skilled and experienced hands *the complete removal of the* tonsil by means of the guillotine is a task of such mechanical difficulty as to be, except in a few rare cases, quite impossible." *Other advantages* claimed are that bleeding is slight, that the pillars of the fauces remain comparatively undamaged, and that it is the only true surgical method for the removal of the tonsil.

With respect to the first of these advantages, S. S. Whillis and F. C. Pybus[2] showed us that in a very large percentage of cases, but not in all, the tonsil can be completely enucleated by what is known as the "reverse" guillotine method. This statement is true as regards the tonsil itself, but not as regards its prolongation over the tongue. When the dissection operation first came into vogue great stress was laid on the fact that this lingual prolongation could by this method be removed. I must state, without denying that inflammation of this "tonsillar rest" may occur, that no case of this sort has come under my personal notice. Moreover, a large number of surgeons, perhaps the *majority, are not in* the habit of stripping this lingual prolongation off the *dorsum of the tongue.* They know how painful the raw surface so produced can be, and either complete their operations with the snare or guillotine.

That the pillars of the fauces are more likely to be damaged in the guillotine operation than in that of dissection no one who is an honest critic of his own handiwork will deny. I *have frequently* been surprised to note that tonsils which I imagined to have been neatly enucleated with the guillotine had taken a portion of the pillars away with them, although I have never found that this had produced a harmful effect. This view as to the damage to the pillars, however, is apparently not held by all laryngologists. Dan McKenzie, for instance, states that "a child's tonsils should never be dissected out. Dissection destroys more or less, usually more, of the faucial pillars .... Enucleation by the guillotine removes the whole of the tonsil yet spares the faucial pillars."[3] The contention that dissection is the only true surgical method of performing this operation is surely unsound. There does not happen to be any other anatomical structure in the body similar to the tonsil requiring similar surgical interference. The case must *therefore* be judged on its own merits; surgical tradition and inclination must, if necessary, be set aside.

Indications for Enucleation by Dissection.

If the above facts are true, one can infer that the outstanding indication for enucleation by dissection in children is the *presence of a* tonsil that cannot, or cannot for certain, be removed by the guillotine. My experience leads me to distinguish three main types of such a tonsil: (*a*) The "chopped" tonsil; (*b*) the small fibroid septic tonsil; (*c*) the "diffluent" tonsil.

(*a*) *Chopped tonsil.*—This type, which happily is becoming increasingly rare, can frequently be dealt with by the reversed guillotine. But as previous inflammation plus trauma and a buried tonsil may imperil complete oblation by this method, it would have to be left to the judgment of the surgeon as to which of the two procedures he would adopt.

(*b*) *Small fibroid septic tonsil.*—This type speaks for itself. It is a small, hard, fibrotic tonsil frequently buried, and with its oral surface sometimes concave. It is not commonly met with in children.

(*c*) *Diffluent tonsil.*—By a "diffluent" tonsil I mean one with a cauliflower-like appearance and somewhat paler than usual. It is usually soft and mushy, with a poorly developed capsule. It is sticky, *often refusing to engage completely* in the window of the guillotine, and is, moreover, difficult to remove by the dissection operation.

Advantages of Reversed Guillotine Method.

So far I have submitted that all tonsils can be successfully enucleated by the dissection operation, and that some in particular can be most satisfactorily removed by this method. In order to decide the more desirable method to employ in that large proportion of cases which can be satisfactorily dealt with by both, we must consider the advantages of the reversed guillotine over the dissection operation.

(*a*) *Time.*—The time occupied is in practically every case very much shorter than in the case of the dissection operation. Leaving out the shortened *period of induction of* anæsthesia, it is reckoned in seconds instead of in minutes.

(*b*) *Anæsthesia.*—The depth and length of the anæsthesia is in nearly all cases shallower and shorter. The statement is nearly correct that whereas a guillotine enucleation can be satisfactorily performed under ethyl chloride or gas and oxygen, a dissection operation cannot. Although their use is *sometimes necessary in many overcrowded* O.P. clinics I do not personally consider that short anæsthetics such as ethyl chloride are always satisfactory. I have sometimes found on examining hospital children at the post-operative weekly inspection portions of tonsil left behind which had escaped the ring of the guillotine in the scramble operation. The type of anæsthesia which is being considered in this connexion is a *light general anæsthesia,* sufficiently deep to allow of the jaw being gagged, without forcing, and whereby the pharyngeal reflexes are not necessarily abolished.

(*c*) *Convalescence and after-pain.*—The primary recovery at hospital and school clinics is of some importance in cases where the children have to go home the same day as the operation. At Charing Cross Hospital, for instance, the children are operated upon between 8.30 and 10 A.M. under the *light general anæsthetic above described.* They are marshalled for inspection at noon before leaving hospital; as a rule *they do not* complain of any severe pain. I am convinced that less traumatism of the tonsillar bed is produced by the smooth blade of the guillotine than by the dissecting strokes of the operator, however delicately the latter may operate. At the same time, I am equally convinced that the gentler the operator the *more he hugs the* capsule and the less he invades the constrictor boundary, the less traumatism, and consequently the less after-pain, is produced. If the capsular surface of two tonsils, one of which has been *enucleated by* the guillotine and the other by dissection, be inspected, it will be found that whereas *the capsule of the former* is smooth and white, the latter has a rougher surface and bears the ruddy tinge of its muscular bed. The shortened secondary convalescence is of equal importance in private practice, when the operation takes place in a nursing home and where expense to the patient should be considered by the surgeon.

Personally, I feel that, in the class of case under consideration, from the patient's point of view the reversed guillotine method is the one to be employed; from the point of view of the operator there is not the slightest doubt that operation by dissection is more satisfactory, being carried out with all the time-honoured surgical ritual. The surgeon takes his time; the blood is duly mopped away with gauze swabs, and inspection of the superior constrictor muscle fibres show the surgeon that his work has been well done, and that the whole tonsil with its capsule has been *removed.* The guillotine operation, per contra, is relatively messy; the surgeon is in a hurry to remove the first tonsil before the little blood that accumulates has had time to obscure the view of the second one. He may instinctively feel that he has effected complete removal, but cannot be certain until he examines the tonsil after removal and, later, inspects the throat at leisure.

A certain number of laryngologists and general surgeons who themselves no longer have to remove tonsils and adenoids en masse in out-patient clinics, never employ any other method in private than dissection, and are loud in their condemnation of any other method. They have been impressed by the advantages of dissection as compared with tonsillotomy, have acquired dexterity in the former operation, and for one reason or another have never troubled to practise the reversed guillotine method.

---

[1] THE LANCET, 1909, i., p. 1313.

[2] THE LANCET, 1910, ii., 875.

[3] Practitioner, 1917.

If tonsils can be adequately removed by a simple, short operation, entailing less discomfort, less risk, shorter convalescence, and less expense to the patient, surely this operation should commend itself to the surgeon anxious to do his best for the patient. I have purposely not emphasised the fact that the technique of the guillotine is simpler to master than that of dissection; because I feel that if the dissection operation were the better in all cases, it should be cultivated, no matter what its difficulties might be; and, in any case, the throat surgeon should be master of both methods, since both have their uses. No good purpose is served by being dogmatic on the subject. When the surgeon has decided that it is in the child's interest to have his tonsils removed, then he should ask himself if they can be removed with the guillotine. Only if they cannot, in my opinion, should he have recourse to the dissection operation. The fact is now generally recognised that the timely removal of infected tonsils and adenoids is one of the most important advances in *preventive medicine*. Considering the very large number of cases that have to be dealt with, it is important that the general practitioner should have a sound method in readiness. I submit that the reversed guillotine method is safe, easy to master, and successful in nearly all cases; moreover, it does not require the assistance of an expert anæsthetist.

Enucleation of the Tonsils in Adults.

The differences between the diseased adult tonsil and that of the child, particularly with respect to suitability for removal with the guillotine, are as follows:—

Shape.—The infected adult tonsil tends to be elongated rather than globular, and is not, therefore, well adapted to insertion into the ring of the guillotine.

Consistency.—The infected adult tonsil is essentially but not necessarily a fibrotic tonsil. Repeated attacks of inflammation have been followed by repeated processes of repair, of which fibrosis is an expression. The organisms and their evil work have penetrated deeper. The fibrosis affects not only the tonsillar tissue itself with its capsule, but also the cellular tissue between capsule and muscle. There may be *no true line of cleavage for the blade of the guillotine to follow*. One must bear in mind that the size of a tonsil is no criterion of its infection. It is in adults that we most frequently find the small fibroid tonsils referred to above, and this of all tonsils is the one which defeats the guillotine and invites dissection.

By virtue of their fibrotic character the vessels supplying the tonsils have lost some of their power of retraction. Hæmorrhage may therefore be profuse and difficult to control. On the other hand, if dissected out at leisure the original line of demarcation may be more easily found and the bleeding vessels clamped. Some surgeons are not, however, in the habit of dissecting out all tonsils in adults. They feel that, in suitable cases, the advantage of a much smaller dosage of anæsthetic, a far shorter operation, and diminished after-pain outweigh the disadvantage of the brisk hæmorrhage that may result.

Conclusions.

1. That the method of operating in cases requiring tonsillectomy should be governed by the type of tonsil under consideration.

2. That in children tonsillectomy should always, except where contra-indicated, be effected by the reversed guillotine method, preferably under light general anæsthesia.

3. That in adults tonsils should preferably be dissected out.

EUGENICS EDUCATION SOCIETY.—The Galton anniversary meeting will take place on Feb. 16th at the Connaught Rooms, Great Queen-street, Kingsway, London, W.C. The Galton lecture will be given by Mr. W. Bateson, F.R.S., at 8.45 P.M., on Common Sense in Racial Problems. The lecture will be preceded by the Galton dinner at 7 P.M. for 7.30, and members are requested to apply for tickets, price 13*s*. 6*d*., at the offices of the society (11, Lincoln's Inn-fields, London, W.C. 2) as soon as possible. The financial position of this society is critical and donations or increased subscriptions are invited.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF
PERSISTENT HICCOUGH
COMPLICATED WITH SPASM OF THE LARYNX.

By MALCOLM SARKIES, M.R.C.S., L.R.C.P. LOND.

IN view of the epidemic of persistent hiccough now prevalent in France the following case may be of interest:—

The patient, a medical man 47 years of age and of rheumatic habit, had contracted a chill a week previously with a rise of temperature to 101° F., accompanied by an explosive cough. On the fourth night after the onset of the chill he was awakened at 2 A.M. with a hiccough which persisted till the morning. After his breakfast the hiccough stopped, but *no sooner he coughed it returned and persisted unremittingly* until more food was taken. It then stopped, only to become active once more as soon as he coughed again. He continued to carry on his practice for three days with the hiccough and then sought aid.

On examination no inflammatory condition of the pleuræ, peritoneum, or meninges could be discovered, nor was there any evidence of intracranial tumour. Reasoning: The vagi nerves along the trachea were stimulated by the cough, the impulse passing to the medulla, whence a reflex was sent down the phrenics to the diaphragm, producing the hiccough.

Therefore, by curing the cough one would hope to cure the hiccough. With this end in view the patient was put to bed on a milk diet, and the treatment was a tinct. camph. co. and squill cough mixture and inhalations of vapor benzoin. co. He was very much worse the next day, for, in addition to the hiccough, he had developed a recurring spasm of the larynx, which entirely prevented egress or ingress of air for perhaps half a minute at a time and which was most distressing to behold. He had had about 25 such spasms and was in a very exhausted condition.

On examination, the whole of the abdominal cavity was tympanitic and his heart was now remitting irregularly. Reasoning: The milk diet in an "acid" subject (rheumatic) produced much flatulence, some of which was belched up, the sudden forceful rush of wind upwards producing a closure spasm in a tired and overstrained larynx.

Therefore, by curing the flatulence one would hope to cure the laryngeal spasms. With this end in view the milk diet was stopped. In addition to the cough mixture the patient was given an alkaline mixture with some ammon. bromid. in it, a saline draught each morning, and the diet ordered was one of boiled fish, chicken broth, and a little thin bread and butter, with half an ounce of whisky in a wineglass of water twice a day.

In 24 hours the spasms were decidedly less severe and less frequent, and in another 24 hours both the hiccough and the spasm had entirely subsided. In the meantime the cough was very much improved.

The hiccough had lasted 6 days and 6 nights for perhaps 20 hours out of the 24, and occurred not as a single hiccough but in a series of 5 to 8 rapid percussions with an interval of a few seconds between each series; and the laryngeal spasms had lasted 48 hours. The patient made a rapid and uninterrupted recovery.

St. John's Wood, N.W.

A CASE OF HICCOUGHING.
ISOLATION OF AN ORGANISM.

By C. E. JENKINS, M.R.C.S., L.R.C.P. LOND.,
PATHOLOGIST TO SALFORD ROYAL HOSPITAL.

A PECULIAR epidemic of hiccoughing has appeared in various parts of the country. It seems to have started in Austria and spread to this country by way of Switzerland and Paris. It appears to be accompanied by *mild catarrhal symptoms* in many cases. A case examined by the writer had a profuse yellow nasal secretion of thin consistency.

Examination of Secretion.

A loopful was divided between two blood-agar plates and well spread. At the end of 24 hours both plates were covered with hundreds of tiny colourless colonies; there were also present five colonies of staphylococcus on one plate and three on the other, so that the organism just described was present in practically pure culture. A film made from one of the colonies revealed a very minute bacillus indistinguishable from *B. influenzæ*. Pleomorphic forms were extremely common and very varied in type. The organism was Gram-negative but did not take any of the ordinary stains well. A fairly strong solution of carbol-fuchsin was necessary in order to obtain a well-stained film. The appearance of colonies and films from subcultures did not differ from those of the original culture. No growth occurred on plain nutrient agar.

The organism certainly belongs to the influenza group, and its minuteness and extreme pleomorphism incline the writer to the belief that it is *B. influenzæ* itself rather than another member of the group. It is, of course, impossible to dogmatise on a solitary case, but if the bacillus of whooping-cough can cause spasm in the respiratory tract it is not unreasonable to concede the possibility of a closely allied organism causing spasmodic contraction of the diaphragm.

A NOTE ON THE

TREATMENT OF NERVOUS INSOMNIA.

BY THEODORE ZANGGER, M.D. ZURICH.

DISTURBANCES of the circulation play an important part in the causation of insomnia; that form of the condition which is associated with myocarditis and heart failure yields not so much to sedatives as to cardio-tonics. In arterio-sclerosis with reduced blood pressure I have found spirit of camphor give good results and also control the accompanying insomnia. Again, in arterio-sclerosis with increased blood pressure, if the kidneys were not diseased, small doses of nitroglycerine given for weeks and months kept the blood pressure almost normal and also relieved the insomnia. Excess of hydrochloric acid often causes irritation of the nerves of the stomach, eructations, and flatulence which contribute to sleeplessness; here an alkaline and dietetic treatment is of use, and I find tabloids of alucol,[1] a colloid hydroxide of alumen, slowly dissolved in the mouth, cure the insomnia.

Combination of Medicinal and Psychic Treatments.

My own treatment of nervous insomnia, which is often the principal and most distressing symptom of an underlying neurosis, consists of a combination of medicinal and psychic treatment.

Medicinal treatment.—For from four to eight days I prescribe 8 gr. of veronal or the soluble sodium veronal or 1½ gr. of dial-ciba to secure from the very first three to six hours of sleep every night, thereby quieting the patient and giving him confidence. Afterwards I give two tablespoonfuls (30 g.) of a solution of sodium bromide (1 in 20) just before supper, and add for a week half-doses of veronal or dial. As improvement continues the latter are reduced to half-doses every other day for a week, and are then completely discontinued. At the end of a month the bromide can also generally be gradually reduced to three-quarters or even half the amount. Of course these doses must be individually modified in each case. The whole bromide treatment lasts from one to three months according to the severity of the case: its action is not only sedative, but successfully combats the mental depression always present during nervous insomnia. As a tonic after the bromide treatment lecithin injections are often of great value. For the past 10 years I have used Professor Sereno's bioplastine, giving an injection three times a week for six weeks.

Psychic treatment.—First of all the physician must investigate the patient's mind in order to discover and discuss psychic shocks which may have originated the nervous disturbances. The patient should learn to confide completely in the physician; the latter must attempt not to bring the patient under the ban of his mental force and power of will, as do hypnotists and the modern school of what may be described as "sexual therapeutists," but to re-educate the patient's mind and will. The physician must also get into private contact with the patient's family or nearest friends to complete his knowledge of the case and to instruct the relatives as to treatment. Near relatives are, however, often most unsuitable companions and advisers, coming, as they may, from a neurotic stock; it may be desirable to remove the patient from harmful home influences for a period of weeks or months, or even permanently to employ a specially trained nurse or companion, or to make use of a medical home.

Satisfactory Results Obtained.

In over a hundred cases of psychoneurosis with insomnia that I have treated in the last five years the results have been satisfactory. I have not found it necessary or desirable to refer at length to sexual matters in more than half a score of cases, and then thoroughly and earnestly. I am greatly averse to the modern system of daily investigation of the sexual life. As Professor O. Veraguth said after a lecture on psychic treatment by the Freudian system, given some 15 years ago by Dr. Jung, of Küsnacht, to the Society of Medical Practitioners of Zurich: "For one complex you eliminate, you produce ten new ones."

Medical Societies.

ROYAL GLASGOW MEDICO-CHIRURGICAL SOCIETY.

TREATMENT OF GASTRIC AND DUODENAL ULCER.

AT meetings of this society held on Dec. 3rd and 17th, 1920, this subject was under discussion.

The Physicians' View.

Professor **RALPH STOCKMAN**, representing the physicians' view, commented upon the unsatisfactory state of our knowledge regarding the ætiology of these ulcers.

Gastric ulcer, he said, is common in anæmic young women; duodenal ulcer frequently occurs in men in the prime of life and apparently in perfect health. We do not know whether they are primary or secondary lesions following upon unrecognised deeper-lying causes. So far the ætiology of the recent clean-cut simple gastric or duodenal ulcer has not been adequately or definitely explained by any of the speculations put forward. It is certain that many people have acute ulcers of stomach and duodenum without any definite symptoms, the ulcers healing of themselves and probably never giving rise to further trouble. Should pain, indigestion, or hæmorrhage betray the presence of an ulcer, clinical experience has put in our hands fairly efficient methods of allaying these symptoms and presumably of inducing healing. Absolute rest in bed, light easily-digested food, attention to the bowels, and the administration of bismuth and earthy carbonates, seem in most cases to cause healing in from three to five weeks. Lenhartz's dietetic treatment was, Professor Stockman thought, on the whole, successful, although treatment was generally stopped too soon. In this way it should be possible to prevent the ulcer from becoming chronic.

Regarding systematic drug treatment designed to produce sound healing, physicians had shown a great want of enterprise. Many patients with gastric and duodenal ulcers keep well for long periods, relapsing under worry, business and domestic strain, or exposure to cold. Anæmia should be carefully attended to. It was, however, the chronic ulcer which gave us trouble in practice. Many of its victims were never free from symptoms, and their working capacity was greatly lowered. While medical treatment had shown lack of initiative, surgery had claimed much. Operation for perforation, pyloric stenosis, deformities, obstruction by adhesions, invasion of the pancreas, liver, and gall-bladder showed brilliant results, but by no means invariably; severe hæmorrhage seldom came into this category. Gastro-enterostomy for the cure of uncomplicated chronic or recurrent ulceration did not stand on a secure basis, and possibly should not be done at all. The strict rest and diet after the operation did good, but recurrence occurred very much as in unoperated cases, and regurgitation of bile was a dreadful sequel to the operation. Moynihan had abandoned gastro-enterostomy in favour of gastrectomy. Mayo advises gastro-enterostomy and burning out of the ulcer. But why operate at all? Perforation was a rare occurrence and could be dealt with efficiently by operation if it did occur. It was claimed that excision of the ulcer prevented the after development of cancer, but if ulceration was the determining cause, cancer should be equally common in the duodenum, which it was not.

The Surgeons' View.

Mr. JAMES H. NICOLL, representing the surgeons' view, said it was impossible to divorce the discussion of treatment from that of ætiology. Gastric and duodenal ulcers differed in two particulars: gastric ulcer tended to become malignant, duodenal ulcer hardly ever. Gastric ulcer was common in young females, duodenal affected middle-aged men. Pancreatitis, along with gastric and duodenal ulcers, were steadily following appendicitis, intestinal obstruction, and cholelithiasis in becoming the object of immediate surgical treatment. The last word in diagnosis lay with the surgeon. For duodenal ulcer, enfolding with closure of the pylorus was the proper course. This necessarily involved gastro-enterostomy. For gastric ulcer, excision or enfolding constituted the treatment; the superaddition of gastro-enterostomy then depended upon the site of the ulcer and the degree of distortion of stomach produced by the excision or enfolding. Concerning points of detail Mr. Nicoll said:—

(*a*) Large parietal incisions should be employed so that the other organs in the abdomen may be examined.

(*b*) Gastric and duodenal ulcers apparently cured by medical means not infrequently relapsed, perforated, bled, or became malignant.

(c) Microscopic examination of all excised gastric ulcers was advisable.

(*d*) When gastro-enterostomy was called for alone or in addition to pyloric closure or excision of the ulcer, in most cases the ordinary posterior operation answered well. Should this lead to bile regurgitation three methods were available. Gastro-enterostomy plus entero-enterostomy; Roux's gastro-enterostomy "en Y"; or a modification of that permitting of side-to-side union.

Mr. Nicoll preferred the third method.

The Practitioners' View.

Dr. R. O. ADAMSON presented the case from the point of view of the practitioner. Dr. A. F. Hurst had recently said that if practitioners and physicians only did their duty, cases of ulcer would never reach the stage in which the surgeon's help was required, from which it was clear that Dr. Hurst had never engaged in general practice. Sooner or later the majority of cases yielded to medical treatment when diet restriction and other treatment were relaxed. Many were cured because treated in their earliest stages. In the presence of proved ulceration the cure was often only partial, as the ulcer was not completely and soundly healed. Once the symptoms had disappeared patients returned to unhealthy surroundings, to food wrong in quantity and quality, naturally with a return of their trouble, which was then more difficult to heal. What was required was prolonged after-treatment in the early cases, for frequent recurrence was apt to be followed by deformities of the stomach, pylorus, and duodenum, which might be worse than the primary disease. Dr. Adamson then considered in more detail how the cases presented themselves to the practitioner.

(1) The type that is brought to our notice first by perforation. In these cases few, if any, symptoms have preceded the perforation, and in these cases the medical treatment only begins when the surgical treatment ceases. In young subjects the prognosis appears to be good.

(2) The type that begins with hæmatemesis, sometimes a pinhole perforation of a blood-vessel. Here also there is often little or no history of previous indigestion. The early recognition of the serious nature of the illness with the consequent prolonged and thorough treatment usually leads to recovery, which is generally enduring.

(3) The large group of cases labelled indigestion, dyspepsia, gastric catarrh, gastritis, or bilious attacks. These cases yield, for the time at least, to rest in bed, rectal salines, or other less drastic measures. In most, recovery is temporary and there is recurrence months or even years after. Many come to the surgeon for perforation or pyloric stenosis and the results of surgical treatment are highly satisfactory.

(4) Duodenal ulceration. This may appear as a simple hyperchlorhydric indigestion which comes and goes, often in the spring and autumn. In definite ulceration our medical treatment meets with success up to a point and chronicity is often established and then hæmorrhage and perforation are likely enough to occur.

He asked: What is wrong with our treatment? The methods are probably not at fault, but after-treatment is not sufficiently prolonged. It should be continued for years, the question of suitable diet being all-important.

Dr. JOHN COWAN said that the mortality of ulcer was considerable.

In a series of 120 patients who were in his wards suffering from some form of ulceration of the stomach or duodenum, 15 died—i.e., 12·5 per cent.; 8 died from hæmorrhage, 4 from perforation, 1 from toxæmia, 1 from exhaustion, and 1 from an unknown cause a few days after refusing operation. He had recommended operation in 21 patients (17·5 per cent.), and in two others operation had been required within a short period of their discharge from hospital. Operation had been performed in 17 cases, seven times on account of recurrent hæmorrhage, seven times on account of dilatation of the stomach, thrice for a perforation. Two of these patients died, both from perforative peritonitis. The ulcer was situated in the duodenum in 10 cases and in the stomach in 6. In the other patient no ulceration could be discovered at the operation. In another patient, who died from hæmorrhage, a small erosion proved the source of the bleeding. Operation was indicated in all cases with pyloric obstruction and in those with peritonitis.

The after-results of operation were still undetermined; only five had answered his inquiries, all being well 3 to 11 years later. The best results were obtained by close coöperation between physician and surgeon and careful examination by every possible means of the particular features of each individual group. In his series the mortality in the operation group was 11·7 per cent. and in the non-operation group 12·6 per cent.

Discussion.

Dr. SOUTTAR MCKENDRICK suggested that operation should be limited to gastric and duodenal ulcers attended with severe recurrent hæmorrhage, pyloric stenosis, gastric tetany, or perforation, or where evidence was present of a localised peritonitis or subphrenic abscess. X rays afforded a reliable guide when the results were carefully interpreted. When the stomach emptied in 5 to 6 hours prolonged medical treatment should be applied to patients resting in bed. Should pyloric stenosis follow operation could be resorted to. The mere presence of occult blood in the fæces was not sufficient reason for operation.

Sir KENNEDY DALZIEL agreed that a large proportion of gastric ulcers required operation, but acute ulcers did not call for intervention until prolonged treatment had first been tried. In America the feeling was in favour of gastrectomy. How many physicians or pathologists had seen a healed chronic ulcer? Professor Samson Gemmell had said that a chronic ulcer never healed. The results of gastro-enterostomy were better than they had been, and he had been struck by the good results of extirpation. Syphilis he did not consider a common cause of ulcer.

Resumed Discussion.

Professor WALTER HUNTER, the Chairman, referred to the question of a syphilitic ulceration of the stomach. In one case specific treatment was followed by cure, demonstrated by X ray examination. He also quoted several other cases treated in diverse ways.

Dr. G. HERBERT CLARK said that our unsatisfactory knowledge of the ætiology of gastric and duodenal ulcers at present precluded much advance in their treatment. Until the physiological functions and actions of the stomach and duodenum were taken into account treatment was liable to be only symptomatic.

The stomach was a muscular organ fixed more or less at both ends, and roughly divisible into a fundic or receiving and a pyloric or churning part. During digestion the pre-pyloric sphincter shows as a constriction. The fundic stomach supplies the pyloric stomach with food and acid juice, which the pyloric stomach churns up and propels against the pylorus, whence it passes on as acid chyme when the chemical and nervous stimulus opens the valve. The natural direction will continue so long as the pylorus is freely patent; and when, from stenosis, it becomes less so, the musculature of the pyloric stomach hypertrophies to meet the new conditions, just as does cardiac muscle. When the stenosis is very great and delay in emptying becomes extreme, the effect of gravity, distension with food and gas, &c., causes great stretching, and as a result the peristalsis loses its force and direction—possibly like an auricle or ventricle in fibrillation. In other words, compensation has broken down. Dr. Clark said that it was not difficult, then, to see why operative interference by gastro-enterostomy very often fails when there is no marked stenosis and consequent delay and dilatation; the emptying of food and acid juice mixture—not properly triturated chyme—occurs far too rapidly and intestinal and other troubles follow. He said that after cutting or cauterising raw injured surfaces were exposed to the gastric juice and the claim that operation removed the source of irritation could not be sound. He considered that the gnawing pain was due largely to muscular action, probably antiperistaltic action to return food unsuitable to the mucous membrane and digestive juices of the stomach concerned. The operation of ligating the pylorus, providing this were fairly patent, could only result in desperate efforts of the pylorus to open when the chemical and nervous stimuli reach their normal reacting point, added to by the forcible pyloric stomach peristalsis behind. No wonder there was gnawing pain. In the presence of marked stenosis, delay, and dilatation, with broken-down compensation, the performance of gastro-enterostomy was almost always brilliantly successful. In its absence failure was far too frequent to encourage its recommendation. If the patient took the same care in the way of rest, diet, &c., without operation as after operation, his relief would generally far outdistance any benefit he would obtain from surgical interference. Severe and uncontrollable hæmorrhage, like perforation, were conditions in which operation had no alternative.

Dr. W. R. Jack said that most physicians agreed as to the type of case suitable for operation, but that surgeons took a wider view. In his experience where, in acute gastric ulcer with hæmorrhage, an operation was performed to ligature the vessel the surgeon invariably failed. In similar conditions medical treatment had repeatedly succeeded. He asked for late results from surgeons and for statistics. Most methods succeeded temporarily, sometimes for years, but he wished to know if surgical relief was greater than medical and more prolonged. We all knew of cases where, after operation, symptoms similar to those occurring previously had persisted. Other cases had substituted an ulcer of the bowel for one of the stomach. He wished to have statistics of cases showing these results.

Dr. H. E. Jones *said that whereas the physician* and the surgeon saw the cases often after long duration, the practitioner saw them before, during, and after treatment. We needed complete statistics over long periods. Dr. Jones referred at length to the different types of case—of ulcer and of simulated ulcer—seen by the general practitioner, and commented upon the probable effect of the prolonged rest after operation upon the body and mind of the patient. He mentioned many different conditions leading to symptoms simulating gastric ulcer, and outlined the types of treatment he found most suitable in each case.

Mr. Alexander McLennan was convinced that in every case all available measures of investigation into the condition should be applied. X rays as well as chemical methods are necessary. Where the stomach is ptosed without pyloric stenosis surgical interference was not indicated, although if an ulcer existed the sufferer was in a most unhappy condition. So also was the patient who after operation suffered from regurgitation of bile with vomiting and distension. He said that the digital stretching of the pylorus for dilatation of the stomach had proved satisfactory. On the question as to whether immediate gastro-enterostomy should follow laparotomy for perforation, Mr. McLennan said that in the hands of his colleague, Mr. W. Campbell, who did not usually perform an enterostomy at the time, many cases did very well without further operation. The Mayo's said that a perforated duodenal ulcer healed better than an unperforated one for some unknown reason. Duodenal ulcers did not heal so well as gastric ones.

Dr. Douglas Russell said that he was becoming increasingly reluctant to advise operation, but believed more in mental and physical rest. Small doses of opium seemed to do good. He gave in detail his [illegible] of the suitability of various foods at various [illegible] of convalescence.

Mr. Archibald Young remarked that only by combining purely medical and purely surgical views could one arrive at a useful conclusion. He agreed with previous speakers that the aids to diagnosis available were often real and reliable. The surgeon had to deal mainly with the chronic ulcer. A proportion of acute cases with perforation or alarming bleeding occurred, but a majority are chronic.

The question therefore arose whether it could be true that a chronic ulcer never heals. Why should it not heal? The suggestion that all symptoms could disappear, perhaps permanently, and the ulcer still remain appeared to Mr. Young inconsistent with the facts of pathology and with the symptoms of disease. Few surgeons had escaped seeing evidence at operations of healed gastric and duodenal ulcers. Mr. Young asked why it was that symptoms of gastric and duodenal ulcers so often vanished in a single night, after days and weeks of almost constant distress. He then proceeded to analyse Mr. Nicoll's thesis that such ulcers should always be treated surgically on the ground that treated medically they frequently may relapse. He suggested that Mr. Nicoll's description of the second remedial operations for the correction of the unfortunate after-effects of the first ones showed that even the surgeon had no reliable panacea for these conditions. Mr. Nicoll had said that he was fast coming to the position that all cases of gastric ulcer should be treated by partial gastrectomy or excision of the ulcer. Mr. Young pointed out that of all those entering into the discussion that evening more than half had been at one time or another victims of the condition and many of the rest also. Were those persons prepared to accept the position that gastrectomy was the only possible treatment? They were not. *His own experience had convinced him that a posterior* (no loop) gastro-jejunostomy, without ligature or closure of the pylorus, was treatment that would give good results in a large proportion of cases. Since the last meeting he had made an inquiry into the subsequent progress of all his private and hospital cases of gastric and duodenal ulcers. So far the results had been more satisfactory than could have been hoped for. Mr. Young concluded by reading two sample replies. He promised to submit to the society later a digest of the complete figures obtained.

Mr. Nicoll, in reply, thought the discussion would do good. He would have preferred the consideration of gastric ulcer separately from duodenal ulcer. "Gastric ulcer" was passing to the position the "appendix" held some time ago. Gastric ulcers tended to become malignant and should be excised. Help was needed *from physicians, pathologists, and physiologists in the* treatment of gastric and duodenal ulcer.

Dr. Adamson, in winding up the discussion, said that the general practitioner saw things from both sides. What is the general practitioner to take out of the discussion? He was driven to the surgeon, at least in accidents and threatened accidents. It appeared that the worse the case the better the result; at any rate the greater the pyloric stenosis the better the result.

MEDICAL SOCIETY OF LONDON.

Pathological Evening: Exhibits.

A meeting of this society was held on Jan. 10th, Sir William Hale-White, the President, being in the chair.

Lysol Poisoning.

Dr. B. H. Spilsbury showed the Stomach and Intestines of a woman, aged about 40, who died about an hour and a half after having swallowed lysol.

Post mortem, brown staining had been noticed on the lips and extending from the angles of the mouth towards the chin. There were also brown staining of the lips on their inner aspect. The epiglottis was eroded, the larynx œdematous, and the air-passages were congested and contained stomach contents smelling of lysol. The urine was clear and did not darken. The tongue was white and furred, the soft palate injected, and the tonsillar surfaces were opaque and grey. The pharynx was also injected and there was some superficial erosion in the pyriform fossæ. The mucous membrane of the œsophagus was injected and in its lower part were superficial erosions running longitudinally. In the stomach was a large amount of brownish fluid mixed with food, with a strong odour of lysol. Its mucous membrane was swollen and dull grey except at the pyloric end, where it was bright red. The change was most marked along the lesser curvature, where the mucous membrane was soft and loosened and showed superficial erosions. The whole stomach wall was thickened, but its external surface was normal. The first part of the duodenum was injected, but the rest was normal. Of the jejunum the first foot was normal, but below this were 4 to 5 feet which were thick and œdematous and very congested, but without erosion.

Throttling.

Dr. SPILSBURY also showed a Larynx from a case of Throttling; it was removed from a woman aged 24.

There had been found post mortem, in addition to the pressure marks on the neck, petechiæ in the right conjunctiva and over the heart. The cricoid cartilage was fractured vertically anteriorly, but there was no hæmorrhage around the fracture. A small hæmorrhage was found beneath the perichondrium covering the posterior surface of the thyroid, and there were minute hæmorrhages in the larynx, chiefly below the vocal cords, and a large hæmorrhage in the wall of the left ventricle of the larynx. The air-passages were congested and contained frothy mucus, and the meninges were congested and their veins engorged. The tongue was slightly indented at its margin by the teeth. The fingers and finger-nails were livid.

Dr. SPILSBURY also showed a specimen of

Angioma of the Spinal Meninges,

from a man aged 42. In August, 1917, three years before death, he was at work, but was gradually getting weaker, and finally abandoned work in June, 1918. In the summer of 1919 he was in a hospital for nervous diseases for 12 weeks, where the diagnosis of lateral sclerosis was made. At the time of his discharge he had practically complete paralysis of the lower limbs. There had been pain in the lumbar region and in the legs. Cystitis and bedsores developed, and death occurred from suppurative nephritis. The spinal tumour was found in the meninges on the posterior aspect of the lumbar enlargement, and consisted of a congeries of markedly dilated and thickened veins.

Sir HUMPHRY ROLLESTON said it was difficult to realise how so soft a tumour could produce a descending degeneration from pressure, and asked whether it was certain that the dilated veins were primary and not secondary, and whether any changes had been found in the cord, and whether any similar tumours were found elsewhere.—Dr. PARKES WEBER said that tumours of this description had usually attracted attention by causing hæmorrhage into the pia-arachnoid or brain tissue in young people. He had never heard of a case in which compression of the cord had occurred.—Dr. W. H. WILLCOX, speaking of the first specimen, said that lysol produced marked whitening of the mucous membrane, and that the stomach was more affected than the œsophagus. He thought that in the case described the lysol must have been diluted three or four times or more.

Dr. SPILSBURY, in reply, said that the cord when first removed showed obvious denting in the region of the tumour. No section of the cord had been made. There were no other angiomata in the body. He had only seen two cases in which hæmorrhage into the meninges had occurred as the result of similar tumours. Surgical interference in one case of angioma at the base of the brain had led to fatal hæmorrhage, and death had occurred in another from rupture of an angioma of the choroid plexus.

Dr. E. H. KETTLE showed a specimen of

Carcinoma of the Thyroid Developing in an Adenoma.

The specimen showed a small rounded tumour about 3 inches in diameter and having a smooth capsule. The centre of the tumour consisted of soft white homogeneous material, which was bounded by the remains of the parenchymatous adenoma. The capsule was formed by compressed thyroid tissue. The central material had the structure of a carcinoma simplex. It was actively growing and was compressing the substance of the adenoma. The specimen was removed from a woman, aged 42, who had noticed the tumour for five years.

Dr. KETTLE also exhibited a specimen of

Malignant Disease of the Rectum,

the last 7 inches of which showed generalised polypoid hyperplasia of the mucosa, with a villous papilloma and two depressed malignant ulcers. There was extension of the growth to the glands in the mesocolon. The specimen was taken from a woman, aged 39, who had suffered from looseness of the bowels, with the passage of blood and mucus, for eight years. She dated her illness from an attack of "dysentery" nine years before. The specimens were shown in view of the infrequency with which the supervention of malignancy on a benign growth could be demonstrated clearly.

Mr. CHARLES A. CLARK described the

Radiographic Appearances of Pyorrhœa.

He also pointed out the value of X rays in the diagnosis of this disease.

It was often possible, he said, to decide by clinical examination that a patient had pyorrhœa, but in some cases the mouth appeared free, whereas on X ray examination the disease was found to be present; moreover, where it was known to exist its actual extent was not always fully discernible without the use of X rays. Changes due to the chronic inflammation which we knew to exist could not be demonstrated by clinical examination. The term "pyorrhœa"—which was synonymous with Riggs's disease, or chronic periodontitis—should be used only in its definitive meaning, whilst "oral sepsis" should be used in the general sense. Oral sepsis was a cause of most of the diseases of a chronic inflammatory nature, and its commonest symptom was lassitude. Patients were easily fatigued, and he thought that in some cases this was the source of that pernicious form of drinking known as "nipping." Radiographs of the teeth should be taken by films placed in the mouth, and the rays should be directed primarily at the apices as well as between the teeth, and overlapping of the teeth should be avoided. In the normal condition external to the root of the tooth was the periodontal membrane, thicker and more succulent in childhood than in adults and becoming thinned in advanced age. Next to this was the layer of compact bone or lamina dura lining the socket. In pyorrhœa the periodontal membrane becomes more or less swollen and there is absorption or destruction of the alveolar margins and of the lamina dura, so that when a radiogram showed absorption of the alveolus and a thickened periodontal membrane we were justified in speaking of the condition as chronic periodontitis. Another point to observe was absorption of the apical portion of the root, and this might be peripheral or might spread from the apex upwards. Abscesses were found at the apex as dark areas of irregular shape and size and ill-defined outline. At the apex of extracted teeth affected by chronic periodontitis a translucency was to be seen which might involve, in long-standing cases, the greater portion of the root. This translucency could not be detected definitely by X rays, but where it occurred the pulp canal became obliterated, and with obliteration one could presume the presence of translucency. It was due to chronic periodontitis, and the teeth in this condition were hopelessly affected. The age of the patient was an important factor in diagnosing the disease, for allowance had to be made for the absorption of bone due to senility.

The PRESIDENT and Dr. WILLCOX spoke of the assistance which they had had from X rays in this connexion and of cases of malignant endocarditis in which the source of the infection had only thus been elucidated.

Radiograms of Diverticulitis.

Dr. R. D. R. CROFTON-ATKINS showed several Radiograms of Diverticulitis, which had been taken by Mr. A. C. Marxer. In many of the cases there had been no symptoms.

Mr. HERNAMAN JOHNSON said that the radiograms demonstrated the advantage of X ray diagnosis after an opaque meal over that after enemata, and also that the characteristic features were seen after the meal had been evacuated. The sacculi often existed without symptoms, and caution was therefore needed in the diagnosis.—The PRESIDENT said that the radiograms were really those of diverticula and not of diverticulitis, for the inflammatory changes were not displayed. Diverticula were present in very large numbers of human beings, but only caused symptoms if they became inflamed or perforated.—Dr. CARNEGIE DICKSON showed an illustration of a radiogram of numerous and well-marked diverticula in an elderly patient who had been free from symptoms.

Dr. W. E. CARNEGIE DICKSON contributed a preliminary note on

Mites as Internal Parasites of Man.

He had recently investigated two cases in which large numbers of mites had been present in very carefully taken catheter specimens of urine.

The first of these was a young adult unmarried woman who had suffered for many years from symptoms variously interpreted by the many doctors whom she consulted as "chronic Bright's disease," "cystitis," &c. In April, 1915, a specimen of her urine contained a small amount of albumin, occasional hyaline casts, and very large numbers of surface epithelial cells, many of them in little sheets and groups, apparently from the bladder, and only very few pus cells. Nothing else of special note was detected. The symptoms continued in spite of treatment, the chief of these being frequency of micturition and constant irritation. Another specimen was examined about three weeks later with much the same result, except that the masses of epithelium were larger and made him speculate on the possibility of their being fragments of some neoplasm of the urinary tract. With this in view, the whole of the rest of the specimen was centrifugalised and the deposit examined for further epithelial masses, when there were seen an oval, clear-shelled body, three adult female mites, a larval form, and several ova. These were at first sight thought to be itch mites which might have been washed into the urine from the pudenda, and that the irritation of which the patient complained might possibly be of the nature of a *Sarcoptes* infection from the external genitals. Further examination showed that they were not *Sarcoptes scabiei*, so before sending the specimens to an expert for identification and to make sure that the mites came from the bladder, Mr. Thomson Walker was asked to cystoscope and remove the urine by catheterisation. On cystoscopic examination there were seen on the trigone of the bladder a large number of closely aggregated little raised hemispherical pinkish elevations, with an occasional detached elevation at the edge of the patch, the whole rather suggestive of grains of boiled tapioca of a pinkish colour. More mites were found in the catheter specimen taken from the bladder at this examination, but not in the urine from the ureteral catheterisation of both kidneys. After a prolonged course of treatment by Mr. Thomson Walker and Dr. Murray Leslie the condition gradually improved, and repeated examinations, over a dozen in number, failed to show the presence of any mites or ova. The mite was identified by Professor Ashworth as *Tyroglyphus* (*Aleurobius*) *farinæ* (De Geer), found usually in flour, grain, stored foods, &c. His diagnosis was based on the characters given by Banks, and he notes that this species has been much confused with *Tyroglyphus siro*, the common cheese mite, which is recorded as having been obtained from fæces and urine, but often regarded as a contamination. In the present case a few examinations of the fæces gave a negative finding. The blood was not examined.

The second case was that of a man of middle age who was suffering from a progressive general glandular enlargement, the spleen also being enlarged, firm, and palpable about an inch below the costal margin. The liver was not palpable, and to percussion its lower margin was about an inch below the costal margin in the right nipple line. The patient was very emaciated. There were firm mobile glands in both axillæ about the size of beans, and similar glands were present above the clavicles and in the groins. The condition was suggestive of lymphadenoma, and the blood was examined and gave the following count: Red cells, 3,930,000 per c.mm.; white cells, 22,000; hæmoglobin, 55 per cent.; colour index, 0·71. The differential count showed 78·34 per cent. polymorphs, 2·70 per cent. myelocytes, and 17·34 per cent. lymphocytes. The count suggested a mild degree of, or possibly a remission in, a mixed leucocythæmia, but the problem arose, when the mite infection described below was detected, as to whether it played some or even the chief part in the causation of the lymphatic and blood condition. In the centrifugalised deposit of a specimen of urine, passed with care so as to avoid contamination, he found two adult female mites, one immature mite, two cast cuticles, a mite in profile (stage indeterminable), and two ova. Numerous large masses of epithelial cells were also present, of much the same characters as in the previous case. Some large cells were a little suggestive of immature ovarian ova. The fæces were examined on several occasions, but always with a negative result as regards the presence of mites. The patient also suffered from severe pyorrhœa, and had had the affected teeth removed soon after Dr. Carnegie Dickson's examination. The patient was catheterised by Mr. Thomson Walker, and in the mixed urine from the bladder there were no whole mites or ova, but several disarticulated legs, perhaps parts of a cast cuticle, were found. Very large masses of epithelial cells were present, similar to those found in the ureteral specimens. A cystoscopic examination of the bladder gave a negative finding, the trigone and other parts appearing healthy. Washings from the bladder also showed no mites in the centrifugalised deposit. In the urine obtained by catheterisation of the right kidney only a single immature nymph was detected. In the urine from the left kidney no mites or ova were found, but numerous large masses of epithelial cells, similar to those from the other side. There appeared to be no clinical evidence of the prostate being the seat of the infection and the point was not investigated further. Specimens of carefully passed urine were examined for several days and several cast cuticles, fragments of legs, &c., and one good specimen of a male *Tarsonemus* were found. A lymphatic gland was excised from the left groin, but the changes noted did not appear to be typical of early Hodgkin's disease, the conditions found being equally common in various other diseases producing a toxic adenitis. The findings appeared to be compatible with some form of leucocythæmia, but the condition in the gland did not appear to correspond specially to that of the blood. It might be that the blood condition was in some way produced by the mite infection, but it was difficult to account for the glandular enlargement in a similar way. He knew of no recorded cases which would help to throw any light on the problem. According to Professor Ashworth, the mites were not the same as those of the previous case and belonged to a different family—the Tarsonemidæ—but he was unable from the material available to identify the species. The literature of the subject was scattered, and Professor Ashworth did not know of anyone who had been working in this country on the subject of Tarsonemus to whom he could refer for information or help. The chief difficulty in the identification was that females predominated, and males, upon which he relied for identification, were extremely few in number. There was no doubt, however, as to the genus being Tarsonemus, which is known as infesting various plants, on which it causes the formation of small galls. There was one previous record (1910) of Tarsonemus in the urine of a patient with cystitis, but Professor Ashworth came to the conclusion that the mites did not correspond with the species previously recorded as occurring in man. The patient soon afterwards became more seriously ill, with symptoms of cystitis and pyelitis, passing, in addition to pus and blood, a number of shreds and small sheets of fibrinous blood-clot containing pus cells, the most probable source of which appeared to be the pelvis of the kidney, or, less probably, the bladder. No mites were found in the specimen. The patient died soon afterwards, but the relatives would not allow an autopsy.

Dr. ALDO CASTELLANI said that the discovery of mites in the urine of human beings after it had been withdrawn aseptically was very important. Mites, however, were not uncommon in lower animals. The parasitic flora of man was very similar to that of the lower animals, and he thought that the parasites found in animals would sooner or later also be recognised in human beings.

Dr. F. PARKES WEBER described a case of

Intrahepatic Cholelithiasis,

with acute necrotic changes in the liver and renal convoluted tubules following ether anæsthesia.

When first seen in 1917 the patient was 52 years of age. She had been more or less jaundiced, or had been intermittently jaundiced for the previous two years, had complained of pruritus, and had often vomited after meals. She had sometimes had pain in the right hypochondriac region, suggestive of cholelithiasis. The fæces were pale and the urine contained bilirubin, urobilin, and urobilinogen, but was free from albumin and sugar, and the Wassermann reaction was negative. The liver seemed to be enlarged, but could not be felt distinctly. In hospital there was never any fever and her condition improved. About a month later the jaundice had almost entirely disappeared, there was no pruritus, the fæces were well coloured, and the urine was free from bilirubin, though there was a slight excess of urobilin and urobilinogen. On leaving the hospital she was told to avoid excess of fatty food and meat, and to spend part of every day in the open air. She was not seen again till 1920, after she had had an attack of hepatic colic, jaundice, and vomiting. The urine contained bilirubin, and there was a swelling in the region of the gall-bladder. An operation was decided upon and she was admitted to hospital. This was performed under general ether anæsthesia and lasted about 1¼ hours. The gall-bladder contained small calculi and dark bile-sand with which also the hepatic duct and common bile-duct were more or less blocked. The gall-bladder was excised and a Y-shaped drainage-tube was left with one limb in the hepatic duct and one in the common bile-duct. After operation dark bile came away by the drainage-tube. Two days after the operation the pulse was 120 per minute and the patient was apathetic and drowsy, as if a condition of cholæmia were commencing. The following day she was collapsed and more or less comatose, with suppression of urine, and she died, despite all treatment. There had been no fever. Post mortem there was no evidence of peritonitis.

The liver weighed 42 ounces and appeared somewhat atrophic. The two hepatic bile-ducts were full of blackish biliary calculi and "bile-sand." Microscopical examination showed a diffuse degenerative change of the hepatic parenchyma; the liver cells had a "woolly" appearance in the stained sections and their nuclei stained badly or not at all. The normal columnar arrangement of the liver cells was indistinct. There was no definite hepatic cirrhosis. The kidneys weighed together 11 ounces, and macroscopically showed no very decided change, but microscopically a diffuse necrotic change in the cells of the convoluted tubules. These cells had the same "woolly" appearance as the parenchymatous cells of the liver, and their nuclei stained badly or not at all. The spleen weighed 4½ ounces, and showed nothing special except thickening of the capsule at one part. Dr. Weber said that he had little doubt that the collapse and suppression of urine and the degenerative changes found in the hepatic cells and the renal convoluted tubules were in great part due to the ether anæsthesia, and were to some extent analogous to the symptoms and hepatic changes met with in cases of so-called "late chloroform poisoning." It was curious that in intrahepatic cholelithiasis, though the hepatic ducts appeared to be blocked with calculi and bile sand, jaundice might be very variable in degree, or even sometimes absent. Rolleston stated that not all patients in whom this condition is found after death have been jaundiced. With regard to non-operative treatment of cholelithiasis with chronic jaundice, Dr. Weber quoted the following example from Van Swieten's "Commentaries."

> "I cured a woman, aged 60, who had suffered from jaundice for 12 years. At the commencement it was intermittent, but in the last year it was continuous. Her whole body was almost black, and her conjunctivæ yellow, so that the unfortunate patient inspired all who saw her with horror. In spring the juice of green grass, whey, &c., were perseveringly employed; during the summer months spa waters, and in winter a large amount of Venetian soap with honey. At length the impacted material in the liver began to be loosened, and a flux from the bowels of six months' duration followed, with the disappearance of all the symptoms. A stinking clayey material was evacuated, mixed with small gritty granules of a calculous nature. The patient, whose strength was sustained by good food, and whose wealth enabled her to afford everything necessary, survived in good health for many years."

Green grass is said to have been given by the old physicians because Glisson stated that calculi tend to form in the biliary passages of stalled oxen in the winter and are voided by the bowel when the beasts return to the green food of the pastures in spring.

Dr. ALEXANDER FLEMING gave a demonstration of some

Plate Cultures of Fæces

to show the great preponderance of streptococci in the intestinal flora of some individuals. The question of intestinal conditions due to streptococci was, he thought, a very large one, but there were at present great difficulties in the way of its proper investigation, as we had at present no good method of classifying the streptococci. It was no uncommon thing to find in the intestine six or seven different kinds of streptococci, and until we had some good method of classifying them and ascertaining which of them were responsible for the various conditions, we must of necessity be working more or less in the dark.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 6th, with Professor HENRY BRIGGS, the President, in the chair, when Dr. A. LOUISE MCILROY read a paper on

The Use of Morphia in Labour.

She said that if a suitable drug could be found for the mitigation of pain during the whole process of labour, much would be gained from its administration. Two drugs had been employed—chloroform and scopolamine-morphine. Chloroform had been of incalculable value in operative obstetrics, but its prolonged administration caused atony of the muscles and diminution of uterine contractions. The need for an assistant to administer it was another disadvantage. As to scopolamine-morphine, most of those who gave it a trial agreed that it was useful in labour, but that it had certain risks. Dr. H. Williamson had summed up the question by saying that it often prolongs labour, increases the frequency of forceps deliveries, and that its most serious drawback is its effect upon the child. Dr. McIlroy held it to be of value in selected cases under constant medical supervision. Some had put down the risks of scopolamine-morphine to the administration of morphia, and had advised that never should morphia be repeated after the one initial dose given in the early stage of labour. There was no doubt that scopolamine-morphine is still in its probationary stage. Dr. McIlroy said that there was very little information in obstetrical literature as to the administration of morphia in labour. Her present preliminary communication was based on a year's work in the women's department of the 82nd General Hospital, B. Section, in Constantinople, where she was acting as gynæcological specialist. The department was created mainly for the treatment of British officers' wives, but a large number of Americans and better-class Turkish, Greek, and Russian women were admitted as obstetrical patients. The Russian patients were especially neurotic. The majority of the patients were primiparæ, for whom a sedative treatment was required. The patients were not selected or excluded because of the possible danger of morphia administration; it was given in the complications of labour and in cases of albuminuria. Morphia was used because it was more easily obtainable than omnopon, which Dr. McIlroy had used in pre-war days with satisfactory results. The usual routine of a hot bath and enemata was carried out at the commencement of labour. The patients were not shaved nor douched. Dr. McIlroy ascribed the absence of sepsis to the fact that no vaginal examinations were made unless in cases where some complication was suspected. No interference, with the exception of the administration of morphia, was allowed unless absolutely necessary, and the patients were kept in a dim light, though isolation from relatives was not always possible. In the first few cases morphia was given with the object of relieving pain in the first stage when patients were excited and frightened. It was found after experience with a number of patients that the drug tended to hurry the first stage rather than prolong it, and it was given in succeeding cases with the primary object of hastening their progress. It caused in some cases an apparent diminution of the uterine contractions as observed and felt by palpation of the abdomen; that dilatation of the cervix proceeded notwithstanding was evidenced in some cases where the patient, while in the first stage, slept after a dose of morphia had been given and awoke refreshed in the second stage. In some cases the head was observed to cause pressure on the perineum when the patient was still considered to be in the first stage. As no vaginal examinations were made except in complicated cases, it was difficult to ascertain progress as far as dilatation of the cervix was concerned, but Dr. McIlroy was convinced that the first stage was shortened. There was, unfortunately, no method of scientifically gauging the degree of uterine contractions. The general effect of morphia on the patient was that restlessness was controlled to a great extent, sleep was intermittent and refreshing, less fatigue was observed and less sickness. Thirst was a marked feature, and the patient was allowed to drink freely. Rupture of the membranes was delayed in a considerable number of cases. Only two cases of asphyxia of the child occurred, one in a Russian patient, badly nourished; the labour was short, and only one dose of morphia had been given. The other was in a breech case, the mother being very anæmic. The first dose was usually given when labour had fully commenced —⅙ gr. morph. sulph. hypodermically in upper arm. This was repeated according to the patient's capacity for bearing pain. If she complained of pain and was restless, or if pains were irregular, another dose was given, usually ¼ gr. Doses in some cases were repeated at intervals of 2–4 hours or 4–6 hours, but no definite rule was laid down. Doses were given throughout the second stage in some of the cases as they helped to diminish the pain, and there was no evidence of retardation. It was surprising how much morphia could be given with so little of its usual effects. The patient slept quietly, an apparently refreshing sleep; no excitement was observed. The smallest dose possible was always given, varying, as a rule, from $\frac{1}{6}$ to $\frac{1}{4}$ gr. In no case was the patient observed to be in a state of mental confusion. The pulse showed little change with the morphia administration. The fœtal heart sounds were also kept under observation. In some cases chloroform was given at intervals towards the end of the second stage, but it was found that only a small quantity was required. The third stage of labour did not appear to be prolonged; the placenta in some cases was expelled spontaneously. There was but one case of adherent placenta, and no case of post-partum hæmorrhage attributable to the administration of morphia. The cases of laceration of the perineum were few, most probably due to the better control of the patient. The umbilical cord was ligatured on the cessation of pulsation; the maternal end was not ligatured. There was less evidence of fatigue at the end of labour, and the puerperium was satisfactory. The milk-supply was not affected. There were fewer forceps deliveries, compared with Dr. McIlroy's pre-war numbers, and this was due to the lessening of fatigue of the patient during labour. Dr. McIlroy quoted two cases with suspected complications in which morphia was given. One was that of a Russian obstetric nurse, III-para. Her first pregnancy was terminated by Cæsarean section with a dead-born child. Her second pregnancy was terminated by pubiotomy, a stillbirth also. On examination a very small degree of pelvic contraction was found. Labour was allowed to proceed without interference, and morphia was given at intervals. A healthy child was born without any complications to the mother. The other case was that of a Greek patient sent in by her doctor for operative removal of a dead fœtus towards the end of pregnancy. The fœtal heart sounds could be heard faintly. Labour occurred and morphia was given. A living child was delivered, breathing normally.

Dr. McIlroy did not advocate morphia as a remedy for the complications of labour but had found it of use in the prevention of some complications and in the diminution of their severity, owing to reduction of fatigue in the patient. The advantages of morphia in labour were its dilating and softening effect upon the cervix, and its calming effect upon the patient. It did not require the constant attendance of the medical practitioner. No risks were observed in its administration, as was evidenced by the small number of forceps deliveries and the absence of asphyxia in the child. Further work was, however, required, and more accurate records would have to be kept of the progress of the labour than was possible under conditions existing in Constantinople.

Discussion.

The PRESIDENT congratulated Dr. McIlroy on her paper. He thought that morphia ought to be more used in labour.—Dr. AMAND ROUTH said that morphia had been avoided in the past for fear of lessening the pains. Dr. McIlroy did not examine patients per vaginam and yet expressed herself as convinced that the dilatation of the cervix was furthered by its use. He asked whether the abdominal muscles in the second stage acted when the patient was deeply under the influence of morphia. He recalled cases reported by himself and Mr. J. D. Malcolm where the spinal cord was paralysed in the region of the fourth or fifth dorsal vertebræ. No abdominal contractions took place except near the ensiform cartilage. Possibly the intervals between the pains were shortened by the morphia.—Dr. H. WILLIAMSON said he had used morphia only in combination with scopolamine, but his experience in the use of omnopon, a substance containing the total alkaloids of opium, had not coincided with that of Dr. McIlroy. He believed the action of morphia was to diminish the sensory impulses; there was no evidence that it influenced the dilatation of the cervix apart from uterine contractions. He suggested that the pain was so much lessened that observers did not notice the contractions, which could, however, be distinguished by a hand on the abdomen. If omnopon was used within two or three hours of delivery the child was sometimes born in a condition of oligo-apnœa. He considered that it might be dangerous to the child if given in the second stage. He thought that certain statements made by Dr. McIlroy, such as that morphia diminished the severity of complications, must at present be regarded as opinions rather than proved facts.—Dr. A. LAPTHORN SMITH said that he had found sodium bromide and morphia gr. $\frac{1}{4}$ of great use in nervous patients.—Dr. J. S. FAIRBAIRN had never used morphia systematically, but only occasionally in order to give the patient rest. Labour must be made more physiological. Emotional and sensory disturbances probably inhibited uterine action reflexly, and poor uterine action was the cause of a rigid cervix. The softening effect of morphia on the cervix probably depended on the better uterine action. The problem for obstetricians was to find the mean between doping the patient and the excessive use of instruments; Dr. McIlroy's work might be most helpful.—Dr. HERBERT SPENCER feared that a longer experience of the use of morphia would diminish Dr. McIlroy's enthusiasm for this drug in labour. In his opinion, opium was better than morphia, but the use of both should be confined to the early stages of labour in neurotic patients.—Dr. HAROLD WALLER asked whether sleep in a recumbent position was not a considerable handicap in labour.—Dr. MCILROY briefly replied.

Mr. PERCIVAL COLE read a paper on a series of 43 cases of

Inoperable Uterine Carcinoma Treated by the Cold Cautery Method of Percy,

which we publish in full in our present issue.

In the course of the discussion Mr. O. T. DINNICK said that the operation, of the value of which he had been sceptical at first, brought a measure of appreciable relief to the patient, and in some cases a reprieve. Though nearly all the cases were from one to two hours under spinal anæsthesia, the absence of shock was remarkable. The cases should, of course, be chosen with some care; the cold cautery could do nothing in uræmic cases. He had been struck by the frequency with which pyometra had been met, and by the relief of the toxic symptoms of the patient when it was exposed. The actual cautery was an escharotic, the cold cautery a coagulant, which, moreover, stimulated the stroma and caused a great formation of scar tissue.—Dr. A. E. GILES pointed out that the successful case of the woman of 35 was a good advertisement, because the prognosis in young women was bad. However, the immediate risks of the operation were definite, while these did not exist in other methods of dealing with inoperable cases. Seven vesico-vaginal fistulæ in 43 cases was a big percentage. Dr. Giles said that for many years he had treated these cases by scraping and packing with gauze soaked in a saturated solution of zinc chloride. Pads soaked with bicarbonate of soda were left in the vagina to absorb drainage and to prevent burning of its walls. The immediate risk was nil and the average duration of life probably one year at any rate. One patient he remembered seeing for three years after this operation.—Dr. H. SPENCER had seen Dr. Percy perform the operation at the Cancer Hospital. He asked what percentage of operable cases had been cured by this treatment. The hot cautery might have an advantage over cold in these cases. A vaginal hysterectomy, coupled with the use of a hot cautery, was at least free from mortal risk. He quoted a case, and showed the specimen, in which he had cut through the growth on one side and had completed the operation by the application of a kitchen poker, heated to a dull red, to the broad ligament. He had seen this case alive and well 12 years afterwards. After use of the actual cautery there was very little pain, and recurrence was never observed in the vagina though sometimes in glands. He agreed that pyometra was more common than was usually thought. In removing the growth before cautery he preferred Doyen's cutting forceps to a curette.—The PRESIDENT congratulated Mr. Cole on the excellent presentation of his subject. His own practice was to operate whenever he could get right round the growth, and the results were good even where there was very little margin. Liquor calcis bisulphitis 1 in 8 gave off sulphurous acid in the presence of a weak organic acid, and was a useful application. In considering length of life of patients it must be remembered that the duration of cancer was understated in text-books, and it was a more chronic disease than it was usually thought to be.—Mr. COLE, in reply, agreed with Dr. Giles on the discomfort to the patient of a vesico-vaginal fistula, and hoped to get fewer of these in his next series of cases. Zinc chloride had formerly been used at the Cancer Hospital, but he could give no comparative figures.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

TUBERCULOSIS GROUP.

AN ordinary general meeting of this group was held at the House of the Society, 1, Upper Montague-street, Russell-square, London, on Friday, Jan. 14th, with Dr. BENJAMIN MOORE in the chair, when Professor EDGAR L. COLLIS read a paper on

The Influence of Dust Inhalation on the Incidence of Phthisis.

Predisposition, he said, was the key-note to the tuberculosis problem, since eradication of the tubercle bacillus was not practicable in the same way as the eradication of the infective agent in other diseases, such as yellow fever and malaria by destruction of the mosquito, typhus of the louse, and enteric by ensuring a pure water-supply. Tuberculosis was an index disease—that is, it is correlated with the death-rate from all other causes, its prevalence being a direct indication of the prevalence of subnormal health in the community. Chief amongst the influences which lower resistance to disease, of which phthisis was a pointer, was the polluted state of the atmosphere, as Brend had shown for the excessive infantile mortality in crowded urban, industrial, and mining centres. The particulate matter found in the atmosphere was composed of viable cells, dead animal and vegetable matter, and inorganic material.

(*a*) Viable cells consisted of the tubercle bacillus alone. In spite of the theory that infection takes place chiefly by the alimentary tract, there was no doubt but that animals could be infected aerially and that, other things being equal, phthisis amongst adults was more prevalent in crowded communities and amongst workers at sedentary occupations, such as printers, shoemakers, and tailors, where aggregation of individuals was the distinguishing factor, though, of course, other factors—e.g., hereditary predisposition, might be incriminated. In these classes phthisis was the only common cause of death in great excess and so could not be due to a general lowering of resistance which, in theory, should produce an excess of deaths from every cause, exemplified by the increased mortality amongst innkeepers and others from the use of alcohol, just as a general increase of resistance, exemplified by the beneficial influence of fresh air on agricultural labourers, should diminish them. Lowered local resistance by dust inhalation would increase the incidence of disease affecting the part so influenced—in the present case, the respiratory system.

(*b*) Dead organic material, so far as phthisis was concerned, consisted of dusts which were either innocuous or were actually beneficial. It might be that dusts were the more injurious the less they approximated in constitution to the elements of which the tissues were composed, while also the particles might act as carriers of the infective agent. The evidence for the beneficial effect of dusts on phthisis was derived from coal-mining and from ganister brick-making, the former appearing to exert an inhibitory influence on the prevalence of phthisis, apart from the fact that there was little personal contact amongst the workers, and hence decreased opportunity of passing on infection.

(*c*) Most inorganic dusts predisposed to respiratory diseases excepting phthisis. Thus limestone, oxide of iron, and plastic clays were inert as regards pulmonary disease of any kind; basic slag, emery, and glass predisposed to pneumonia and bronchitis, but not to phthisis. Harmful dusts were those which contained free silica, and silica was an acid which, chemically, belonged to the same group as carbon, with which it shared the capacity to form colloidal compounds.

Professor Collis said that consideration of all the facts regarding the getting of coal, together with the "ripping" of the rocks with which it was mixed in the different coal-fields in relation to respiratory diseases, showed that on some coal-fields there was exposure to injurious dust containing silica which caused bronchitis and pneumonia and would cause excess of phthisis were it not for the coal-dust, which in some way interferes with the effect of silica in causing phthisis. On other coal-fields, where exposure to silica-dust was less, bronchitis and pneumonia were less prevalent and the favourable incidence of coal-dust was greater. Ganister was a quartzite rock containing upwards of 98 per cent. of silica used in the making of first-grade bricks, second-grade bricks being made of ganister containing an admixture of fire-clay derived from the coal-measures. Makers of the former had a heavy mortality from tuberculous silicosis (37 per 1000, as compared with 1·0 for ordinary brick-makers). The position thus appeared to be that silica, an acid material, reached the lungs in fine particles, and set up a reaction which resulted in the formation of fibrous tissue—i.e., silicosis—and lungs so damaged fell a ready prey to the tubercle bacillus. The property of forming colloidal compounds was interfered with by the presence of acids, which suggested that the increased plasticity of fire-clays by long "weathering" might be due to the washing away of organic acids derived through fire-clay from coal. When silica-dust was inhaled with raw fire-clay dust it might be that the organic acids in the latter prevent the silica particles from becoming colloidal before they are removed by phagocytic action. Fine silica-dust, not so prevented from becoming colloidal, might enter into the colloidal carbon compound, the protoplasmic tissue of the lungs, with the formation of a silica-carbon compound which we know as silicotic fibrosis, and that this tissue, of low metabolic activity, fell an easy prey to the tubercle bacilli. This theoretical reaction was akin to that proposed by Llewellyn for the formation of the tophi in gout, biurate of sodium being deposited in an organic framework; it did not contradict chemical theory, nor was it in opposition to Haldane and Mavrogordato's adsorption theory. The purely mechanical explanation depending on the hardness and sharpness of the particles would not suffice. The chain which determined tuberculosis might be said to have three links: (1) latent capacity—inherited predisposition; (2) the conversion of latent into real capacity, whether through trauma or other interference with normal metabolism; and (3) infection. The second of these was the biochemical link, and the problems which demanded solution were (1) what influence fine silica particles alone exerted on the tissues; (2) whether or not this influence was affected by the presence of fire-clay; (3) what influence coal-dust exerted on the tubercle bacillus; and (4) the relation between fibrous tissue and the tubercle bacillus. We must, he said, recognise, though we cannot yet explain, that the coal-miner experiences an unusually low mortality from phthisis.

The paper was illustrated by many tables, and after a short discussion the lecturer was given a very hearty vote of thanks.

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND.

A MEETING of this society was held in the Medical School of the University of Leeds on Jan. 7th and 8th, with Professor M. J. STEWART in the chair.

Professor J. S. DUNN (Birmingham) described a fatal case of Chorea, in which a considerable number of embolic and thrombotic lesions were found in the brain with a few in the kidneys. There was no endocarditis or other obvious source of emboli and no naked-eye infarcts.—Professor H. S. RAPER (Leeds) had analysed a Human Enterolith of undescribed chemical composition; it consisted of fatty acids, fat, and cholesterol, with 72 per cent. of unconjugated bile acids almost entirely choleic acid.—Professor J. H. TEACHER and Dr. J. H. PRINGLE (Glasgow) gave a further account of Antemortem Digestion of the Œsophagus as a cause of Hæmatemesis especially after operation; and Professor E. E. GLYNN (Liverpool) described another series of cases. Stomach contents with active gastric juice are brought into the œsophagus by vomiting and may there produce serious ulceration, which is capable of healing; the œsophagus should be washed down after vomiting.—Professor STEWART (Leeds) demonstrated a Malignant Sacro-coccygeal Chordoma, and with Dr. W. H. M. TELLING (Leeds) a Primary Cancer of Liver in a case of Hæmachromatosis.—Professor R. MUIR (Glasgow) showed another example of a Malignant Hepatoma in a child.—Professor J. K. JAMIESON and Mr. J. F. DOBSON (Leeds) communicated the results of their inquiry into the nature of the lymphatic system, and strongly upheld the view that the lymphatic vessels end peripherally as closed tubes, and do not open into the tissue spaces.—Dr. H. W. CROWE (Harrogate) gave a demonstration of the facility with which streptococci could be differentiated in his medium of defibrinated blood three parts, trypsin agar one part, with 1 per cent. of dextrose sterilised in plates by successive heating to a "chocolate."—Dr. T. TANIGUCHI (Glasgow) had tried the Wassermann and Sachs-Georgi reactions in parallel in a considerable series of sera and found very few discrepancies. He also described experiments showing that rabbits injected with guinea-pig tissues or lipoids develop hæmolysin for sheep blood corpuscles and also become reactive in the Wassermann reaction.—Dr. N. YOSHINARE (Glasgow) had studied the hæmolysin for guinea-pig corpuscles which is normally present in ox serum; evidence of the independent existence of immune body was not obtained directly, but in filtrates through porcelain some combination with red corpuscles was found.—Professor C. H. BROWNING, Drs. E. M. DUNLOP, and E. L. KENNAWAY (London) find that the Wassermann reaction may be positive with unheated normal sera if too much alcohol is added to the system with the organ extract.—Professor BROWNING, Professor J. B. COHEN, and Miss R. GULBRANSEN (Glasgow and Leeds) had examined the antiseptic potency of a number of new compounds allied to acriflavine but had found none superior to the original diamino-acridine methyl chloride.—Drs. J. W. MCLEOD and P. COVENLOCK (Leeds), in an extensive inquiry into the production in bacterial cultures of diffusible substances with specifically inhibitory properties, obtained a number of results indicating auto-inhibition.—Dr. MCLEOD and Dr. G. A. WYON (Leeds) could find no clear evidence in favour of vitamines being important to promote bacterial growth.—On behalf of Dr. P. B. WHITE (Aberdeen), Dr. J. CRUICKSHANK gave a demonstration of *Tarsonemus Woodi*, the mite recently implicated as the cause of the Isle of Wight bee disease.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

ON Jan. 7th a pathological meeting of this society was held at the West London Hospital, Dr. F. J. MCCANN, the President, being in the chair.

The following specimens were shown:—

Mr. MCADAM ECCLES showed: (1) A Toothbrush removed from the stomach on the day on which it had accidentally been swallowed. It was found partly through the pylorus. (2) A Clinical Thermometer removed from the urinary bladder of a young girl who for 18 months had had frequency of micturition and hypogastric pain. Cystoscopy revealed the thermometer surrounded by a phosphatic calculus. (3) A Chondroma of the Testis in a man of 33. It was associated clinically with a hydrocele. The testis was small and very hard, and microscopic section showed that hard cartilage had almost entirely replaced the body of the testis. (4) A "Teratoma" of the Testis removed from a man of 34 with six months' symptoms of enlargement with very little pain. Microscopically an encapsuled growth consisting of areas of "sarcomatous" type of tissue in which were numerous blood spaces, together with areas of scattered and ill-formed cartilage.

Dr. W. H. WILLCOX showed: (1) The Œsophagus and Stomach of an Infant, aged 9 days, who died from poisoning by carbolic disinfecting fluid. The child had been spoon-fed, and probably a spoonful of the fluid had been given in mistake. The stomach showed a black corroded area. Analysis of the disinfecting fluid showed that 3 per cent. of phenols were present. (2) The large Intestine and Rectum of a Man of 24 who died of amœbic dysentery in spite of full treatment by emetine, vaccine treatment, and colonic irrigation through a cæcostomy opening. Extensive ulceration was present in the cæcum and rectum. Microscopic examination of the ulcers showed the typical appearances found in cases of amœbic dysentery.

In reply to Mr. ASLETT BALDWIN, Dr. WILLCOX said irrigation with copper salts had not been used in this case.

Mr. O. L. ADDISON showed a Kidney removed by Nephrectomy from a man of 43 with a two years' history of hæmaturia. Sections showed a papillo-adenocarcinoma.

Mr. TYRRELL GRAY demonstrated a Myxo-sarcoma of the lower end of the femur in a woman of 60 removed by disarticulation at the hip-joint.

Dr. H. J. F. SIMSON showed: (1) A large Pelvic Tumour involving the rectum, uterus, and vagina, which on microscopic examination proved to be a lymphadenoma of the rectum; (2) a Tumour of the Round Ligament of the Uterus of uncertain origin.

Mr. SYDNEY MACDONALD showed two specimens of Papillomata of the Pelvis of the Kidneys. In one case definite carcinomatous changes, as shown by the microscope, had taken place at one spot. In this case recurrence had taken place in the nephrectomy scar. In the other case the growth was a typical papilloma and was associated with similar growths in the bladder.

Dr. J. BURNFORD showed two cases of Cirrhosis of the Liver, both of the multilobular type and definitely not associated with alcoholism. In one, a female of 24, ascites had rapidly developed and the spleen was also enlarged.

Mr. N. F. SINCLAIR showed: (1) The Pyloric Half of a Stomach the seat of two chronic gastric ulcers, one of which had been adherent to the pancreas. Partial gastrectomy had been done. Microscopically there was no evidence of malignancy. (2) A specimen of Volvulus of the Cæcum and Ascending Colon in which excision of the volvulus and ileo-colostomy had been done. (3) A spleen of normal size excised for traumatic rupture. Extensive laceration of the under surface with escape of the diaphragmatic surface had occurred. Acute symptoms developed 6 days after injury.

Dr. R. R. ELWORTHY showed: (1) The lower 18 inches of the large intestine after administration of ether by the rectum; (2) a slide showing an adeno-carcinoma of the cervix uteri.

Mr. B. SANGSTER SIMMONDS showed: (1) A Tibia the seat of extensive Acute Osteomyelitis. The knee-joint was infected. Drainage of the medulla of the tibia and of the knee-joint having failed to improve the general condition, amputation of the leg had been resorted to with success. (2) A Periosteal Sarcoma of the Femur in a girl of 18. Microscopically the growth showed great vascularity with myxomatous changes in parts.

Dr. J. E. EARNSHAW demonstrated various organs from a child aged 10 weeks, showing generalised miliary tuberculosis.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING was held on Jan. 11th at the Elizabeth Garrett Anderson Hospital, with Mrs. FLEMING, M.D., in the chair.

Dr. MARY BELL read a paper on

Psychological Forgetting in Relation to Lying, Giving of Evidence, and Medical Histories.

Dr. Bell said:—

The problem of life for each one of us is a problem of adaptation. The experiences of life press more or less hardly upon us, and our weaknesses and strengths are the resultant of the conflicting forces to which we are exposed, and the characteristics we exhibit are the measure of our ability or inability to make satisfactory adaptations to the stress of our environment and the strains of our personality. These reactions are primarily irrational—that is, they are not the result of reasoned thinking. For instance, the first child of a family is apt to be the centre of attention, and to come to regard itself unconsciously as the hub of the universe. When the next baby arrives the first has to make an adaptation and to learn that the parents now no longer give him their whole attention, nor do they demand from him so many signs of affection. If he does not adapt successfully, part of his libido will expand itself into jealousy, fits of naughtiness that draw attention to himself, or into phantasies of being misunderstood, and such emotional and irrational reactions will form the seeds of future characteristics of his personality, and will unconsciously lead him to defend himself from learning his unimportance by making him tend to dominate others and to manipulate situations to his own advantage. Such a complex may easily lead to lying and thieving in some cases, and it is important to remember that the causative complex is subconscious and that consciously such a person may have very high ideals of truth and honesty. We are all of us more or less victims of such complexes.

Dr. Jung says that in the case of normal people the principal function of the unconscious is to effect a compensation and thus produce a balance; and the irrational unconscious emotions have a curious way of acting as the God who tempers the wind to the shorn lamb. I know a lady possessed of a rather unusually good memory who was recently quite unable to recall her husband's regiment, though he had been two years in camp, during which time she must have addressed some 200 letters to him. In her case it seemed probable that the repressing factor was the unconscious wish to forget the emotional suffering caused by the fact that on two occasions he had been dangerously ill during this time. Similar repressions were noticeable in many soldiers who suffered from shell shock with amnesia. The forgetting (in cases where a physical factor due to commotio cerebri could be excluded) was a reaction to horrors seen and experienced.

I submit that in a like way psychological forgetting mars the accuracy of many medical histories. Freud gives several instances of this. Again, it seems that our tendency to replace accurate by phantasied memories should be considered much more seriously in courts of law. Take a case like the recent Greenwood poisoning case in which a year elapsed between Mrs. Greenwood's death and the final trial. Which one of us could remember the details of any one Sunday in 1919? It is true they might remember events during the evening when it was realised that Mrs. Greenwood was seriously ill, or if the possibility of poison had arisen at once they might have reconstructed the events of the earlier part of the day and kept them in mind, but as far as we know there was no intensity of feeling attached to the forenoon of that day. Any evidence given for the first time, 6–9 months later, as to whether Mr. Greenwood went into the pantry or no, or as to who drank wine on that particular Sunday must, to my mind, be pure phantasy. A remarkable instance of phantasied memory occurred also in the Tichborne trial, where the claimant was accepted from the first as her son by Lady Tichborne, though he differed completely from him in physique, in way of speech, and though she even recognised that the accounts he gave of past events were very confused and differed from her own.

Dr. Bell's paper was followed by a short discussion, in which Dr. Helen Boyle, Dr. J. E. Payne, Dr. Grace Briscoe, Dr. Eleanor Lowry, and others took part.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—An ordinary meeting will be held at 11, Chandos-street, Cavendish-square, London, W., to-day, Friday, at 8.30 P.M. A paper on the Influence of Humidity on the Life History of Mosquitoes and on their Power to Transmit Infection will be read by Lieutenant-Colonel C. A. Gill, I.M.S.; and demonstrations will be given by Mr. A. Bagot on Rickettsia in the Bed Bug, and by Dr. P. Manson-Bahr and Dr. A. L. Gregg on Sigmoidoscopic Diagnosis of Amœbic and Bacillary Dysentery.

HARVEIAN SOCIETY OF LONDON.—The annual general meeting was held on Jan. 13th, when Dr. G. de B. Turtle was elected President for the ensuing year. Dr. W. Hill, the retiring President, delivered an address on the Great Advances in the Methods of Treatment of Diseases of the Œsophagus during the Present Century. The adjourned debate on the Future of the Poor-law Infirmary will be held at the Paddington Town Hall, Paddington Green, on Thursday, Jan. 27th, at 8.30 P.M., and will be opened by Dr. A. G. Stewart, of the Paddington Infirmary, and Dr. R. Dudfield, Medical Officer of Health for Paddington.

Reviews and Notices of Books.

PHYSIOLOGY AND BIOCHEMISTRY IN MODERN MEDICINE.

Third edition. By J. J. R. MACLEOD, assisted by ROY G. PEARCE, A. C. REDFIELD, and N. B. TAYLOR. London: Henry Kimpton. 1920. With 243 illustrations, including 9 coloured plates. Pp. xxxii. + 992. 42*s*.

THE outstanding feature of the book, which has run to three editions in as many years, is its modernity; the clinician reading it should find it no difficult matter to get au fait with current literature in any modern branch of physiology; the student who uses it as a text-book will carry into the wards an intelligent appreciation of modern physiology as well as a foretaste of its value in medicine; and the professional physiologist who can read the book without learning something can congratulate himself on being well read in his own subject. The fact that Professor Macleod is familiar with the work on both sides of the Atlantic lends still further charm to this excellent volume. The general impression given therein is one of sound common sense. The author is neither so astigmatic as to draw a distorted picture of modern physiology, nor so myopic as to ignore the great names of the past, nor yet gifted with such sublimely distant vision as to be unconscious of the existence of contemporaries, and so far as one of the latter is able to judge he appraises both liberally. This broad and sensible outlook is perhaps to some extent due to the fact that he has spent some of his best years in a young and virile country, but whatever its cause it is a matter for congratulation.

The first five chapters, dealing mostly with elementary chemistry, though clear and good, are perhaps superfluous, and add to the size and price of the book; the same applies, almost without exception, to the coloured plates. Among the best chapters are those dealing with the regulation of neutrality, acidosis, circulation, respiration, metabolism and vitamines, endocrine organs, and the central nervous system. One would have liked to have seen more about the recent work on the interpretation of electrocardiograms—for example, in connexion with auricular flutter and fibrillation. Modern physiological writings tend to run rather too much on the lines of pH and CO_2, and it is well, if only at times, to recollect that these are not the alpha and omega of physiological knowledge. The subject of internal respiration, so intimately fundamental to life, is dismissed, as in most books, rather curtly with a discussion of the properties of hæmoglobin; but perhaps one may assume that any really full discussion of the question would have led the author too far from the purpose of the book. One might ask, however, what are diabetes, or alcaptonuria, or perhaps even cancer, if not abnormal tissue activities associated with abnormal respiratory exchanges? Examples of the value of physiology to practical medicine are the chapters on the capillary circulation, surgical shock, diabetes, the therapeutic uses of oxygen, or, with limitations, the clinical uses of electrocardiography.

Perhaps unfortunately, perhaps not, the usual stereotyped chapters on reproduction, special senses, and nerve-muscle physiology are omitted from the book altogether; there is also no connected chapter on the functions of the liver, which, as it is quite a useful organ and much in evidence in the wards, is a pity. In view of some of these omissions one would hesitate to recommend it, at all events as the sole book, for the use of students preparing for their intermediate examinations in medicine, but it is so excellent in other respects that these difficulties could readily be overcome, for in spite of its title, the volume is in reality a text-book of physiology. The American spelling is also unsuited to students, who might suffer in examinations if they used such words as *edema*; the same applies to the use of casein and paracasein for caseinogen and casein. The collaborators, by introducing specialist knowledge on respiration, the central nervous system, and the neuro-muscular system, have materially helped in giving vitality to the production. The orthography of Russian names is irregular, some of these (e.g., Pavlov) being spelt according to English phonetics, while others (e.g., Borisov and Savitch, which are spelt Borisow and Ssawitsch) are phonetically German.

The index is clear and adequate, and the references well chosen.

Professor Macleod has really written this book in order to help the rapprochement of the estranged subjects of physiology and medicine. It will therefore appeal rather less to the student of what is now called "General Physiology" in its widest sense than ,to those who are to become clinicians, or those who, having become such, find their education incomplete. Physiology can no more be ignored at the bedside than in the Intermediate Examination Hall. The hearty reception which has been accorded to this work in its earlier editions makes one dare to hope that the day may not be far distant when the candidate for higher degrees in medicine may be required to show, not merely that he has not forgotten his physiology, but that he has so digested it as to be able to use it intelligently in his daily work. For it is certain that in the future the physician with only clinical and classical knowledge will, though cultured, be imperfectly equipped for his task.

Gastric and Duodenal Ulcer.

Symptoms and Treatment. By Dr. EUGEN ROSENTHAL, Budapest. Berlin: S. Karger. 1920. Pp. 72. M.12.

IN a book of 72 pages, illustrated by ten well-printed plates which are mostly reproductions of X ray photographs, Dr. Rosenthal gives the results of three and a half years' investigations on all gastric cases presenting themselves at the University Hospital, Budapest. Of these 3500 cases 326 had ulcers. The investigations have been carefully carried out and the results examined and set down in tabular form. Four-fifths of the book is devoted to methods of investigation and diagnosis, and the question of X ray diagnosis is dealt with in special detail and with admirable clearness. In the whole series the proportion of duodenal to gastric ulcers was roughly 1 to 2. Ulcers were twice as common in men, but whereas in gastric ulcers the preponderance of males was only slight, in duodenal ulcers it was 9 to 1. It is noteworthy that the incidence of the various ulcers in this general series is very different from that in recently published surgical statistics, where the number of duodenal ulcers has been much higher. The author examines in turn the diagnostic value of the various symptoms and finds, on the whole, that the history can only indicate that an ulcer is probable, and is of very little value in determining its site. The nature, site, and time relations of the pain he finds to vary considerably and sometimes to be quite misleading, one ulcer of the lesser curve, for instance, giving a typical history of hunger-pain coming on two hours after meals and relieved by food. Coming to investigation methods, he places little reliance on tests for occult blood, except in the differential diagnosis between ulcer and carcinoma. It was only found consistently in ulcers where there had recently been hæmatemesis or melæna; in cases with no manifest bleeding, the occult blood always disappeared after six days' dieting. He is unable to base a conclusive verdict on chemical analysis of test-meals, but finds that there is a definite relation between hyperacidity and site of ulcer, over 50 per cent. of those in the pylorus and duodenum and only 25 per cent. of those on the lesser curve showing hyperacidity. The method used was the single test, which has here been largely replaced by the fractional test-meal. On the whole, he places most reliance on X ray investigation with examination for localised tenderness to pressure controlled by the screen. The line of medical treatment adopted calls for little comment, except that the advocacy of atropine is of interest in view of Bennett's recent findings that this drug will lower the secretion curve of a hyperacid stomach. The conclusion that no ulcers except those accompanied by stenosis or hour-glass deformity should be treated surgically will, however, find very little support, while the statement that hyperacidity is more permanently reduced by medical than by surgical means is in direct opposition to experience in this country and in America. The number of cases treated surgically was small, but in these there was an operative mortality of 13·9 per cent., while in the series of 326 investigated there were 24 post-operative ulcers, figures which perhaps explain the author's conclusions.

Dr. Rosenthal's investigation forms a useful contribution to the literature of gastric and duodenal ulcer, coming at a time when there is an undoubted tendency on the part of writers to overstate the frequency of the "typical" case.

A Short Practice of Midwifery.

Eighth edition, revised. By H. JELLETT, B.A., M.D., F.R.C.P. Irel., late Master, Rotunda Hospital, Dublin. London: J. and A. Churchill. 1921. With 4 coloured plates. 1920. Pp. 548. 18s.

SO short a time has elapsed since the appearance of the last edition of this well-known text-book that very little revision has been called for. We notice that the author in cases of eclampsia in which ordinary medicinal treatment as carried out at the Rotunda Hospital has failed, suggests Cæsarean section as likely to give good results. The account of the treatment of these cases is interesting in view of the good results obtained by the Dublin methods. He does not favour Cæsarean section as a routine treatment of placenta prævia, but points out that the danger to the mother is not likely to be lessened by this procedure. A work of which 30,000 copies have been issued, and which is quite one of the best of the shorter text-books of midwifery, requires no further recommendation from us.

Die Lipomatosis und ihre Klinischen Formen.

By HANS GÜNTHER. Jena: Gustav Fischer. 1920. Pp. 216. M.40.

THE condition of lipomatosis is an interesting one from various points of view. Though the ætiology is still obscure, it is evident that it has some relation to the histogenesis of adipose tissue. For the sites where lipomata occur most frequently are also those where the primitive fat organs are formed in the embryo. Further, there is evidence that some of the endocrine glands affect the growth and metabolism of adipose tissue. In fact, one of them, the cortex of the adrenal, is always loaded with fatty material and might well be described as a glandular adipose tissue. Unfortunately the author of this monograph issued from Strümpell's clinic in Leipzig does not attempt to deal with these aspects of the subject. He describes an affection of adipose tissue in which there is an increase of this tissue restricted to definite circumscribed parts of the body. To this condition the term "lipomatosis" is applied. It is distinguished from the condition of "adipositas" where there is a general increase of adipose tissue all over the body. Single lipomata are by definition excluded from this condition of lipomatosis. The author distinguishes four groups of this condition. 1. *Lipomatosis indolens*, when multiple lipomata occur unaccompanied by any special symptoms. 2. *Lipomatosis dolorosa*, where there is always the symptom of pain (Dercum's disease). 3. *Lipomatosis atrophicans*, when the occurrence of multiple lipomata is always associated with a general disappearance of fat in the body. 4. *Lipomatosis gigantea*, where there is also a hypertrophy of other kinds of tissues, in other words, a partial gigantism. The author has collected a vast amount of clinical material recorded in the literature and added thereto some cases of his own, and he discusses the pathological anatomy, ætiology, and therapeutics of these different types of lipomatosis. His account of the histogenesis of adipose tissue is, however, extremely sketchy, and it would appear that he has not made a careful study of the very extensive literature on this subject. He ignores also the physiology and pathology of the endocrine glands. He does not mention the adrenal gland even where the subject-matter he is dealing with obviously calls for a reference thereto; for example, among the organs where there may be a physiological deposition of fat. In a record of a post-mortem examination of one of his cases of lipomatosis atrophicans he concludes (from naked-eye appearance apparently) that thyroid, hypophysis, and testis were normal, and omits any account of the condition of the cortical lipoid in the adrenal.

With all the extensive material which the author has collected the problem is left very much where he found it, and the volume scarcely justifies the claim made in the sub-title that it is "a contribution to the physiology and pathology of adipose tissue." An extensive bibliography, though by no means complete, forms a valuable part of the book.

FIRST LINES IN DISPENSING.

Second edition. By E. W. LUCAS, C.B.E., F.I.C., F.C.S., and H. B. STEVENS, F.I.C., F.C.S. London: J. and A. Churchill. Pp. 182.

THIS book contains excellent advice for those undergoing elementary courses of instruction in dispensing. Although the book is mainly introductory, a great deal of very useful information has been incorporated, and the sections on prescription writing and incompatibility are helpful to prescriber and dispenser alike. Explanations are clearly given, and the illustrations add to the general lucidity. In the new edition a section on ampoules and a table of solubilities have been added, and general pharmacy is more fully treated. The whole is thoroughly up to date; the suggestion, however, that one pan of a dispensing balance may be made of platinum "if money is no great object"—platinum being now worth more than four times as much as gold—is reminiscent of other days. This little book admirably fulfils its purpose as an introduction to the subject, and can be thoroughly recommended.

DISEASES OF THE THROAT, NOSE, AND EAR.

By DAN MCKENZIE, M.D., F.R.C.S.E., Surgeon to the Central London Throat and Ear Hospital. London: William Heinemann. 1921. With two coloured plates and 199 illustrations. Pp. 646. £2 2*s.*

IN spite of the multitude of text-books on the throat, nose, and ear, the advent of a new one, not merely a new edition, and one of an imposing size, is an event of some importance. The first part of this book contains a conscientious amount of diseases of the upper air-passages. The sections on the ear are the longest and by far the best, and contain an excellent simple description of the functional testing of the labyrinth and an unusually good account of the clinical aspect of the various forms of chronic deafness, which do not always conform to the standard tuning-fork tests. There are included several sections on subjects not usually included in text-books on the nose, throat, and ear—namely, on the thyroid gland, tongue, lips, and gums; these are not complete enough to be of real value, and might well be omitted in any future issue to make room for fuller discussion of more relevant matters.

The author states that the book has been written from the practical point of view, but that limitation of space has rendered it impossible to describe many modifications and variations of operations. But it could be wished that he had provided a more thorough description of the after-treatment, for instance, of the radical mastoid operation. No mention is made of the troublesome after-contraction which so often prevents a good result; moreover, the indications for this operation in chronic aural suppuration receive but scant attention. There is no reference to the method of immediate closure of the wound after the Schwartze operation. For the removal of tonsils and adenoids Dr. McKenzie prefers the patient to be in the sitting position, apparently at any age, and, it would seem, recommends chloroform in these circumstances—surely bold advice.

MEMORIES AND MUSINGS OF A HOSPITAL SURGEON.

London: Macmillan and Co.; Glasgow: Maclehose, Jackson, and Co. 1920. Pp. 192. 7*s.* 6*d.*

THIS little book may have an interest for laymen, but to all medical men who have worked in large hospitals the "Memories" will be perfectly familiar—that is to say, most of them will, though we envy the "Hospital Surgeon" for one of his experiences related on p. 88 et seq. We ourselves remember a man who went round the hospitals some forty years ago, not as a would-be patient, but as a demonstrator of the fact that he could produce at will nearly every dislocation known to surgery. But the patient in the book before us could in addition contract his abdominal muscles so as to drive the abdominal contents so far into the chest that the skin of the abdomen could be made to touch the front of the spine. The "Hospital Surgeon" refers to the fact that heavy drinkers and those affected with syphilis are bad subjects for operation, but we think that the pathology of the case cited (p. 28) is a little crude. It is misleading at least to say that an alcoholic patient who sustained a lacerated wound of the thumb followed by gangrene suffered this complication "because his drinking had so damaged his kidneys that they were unable to cleanse the blood of the poison." The best part of the book is the last chapter, upon "Hospitals and Medical Teaching in the Future," in which chapter there is much sound sense.

PRÉCIS D'UROLOGIE.

By FELIX LEGUEU and EDMOND PAPIN. Paris: A. Maloine and Fils. 1920. Pp. 710. Fr.50.

THIS book is a précis of genito-urinary surgery, containing neither theoretical considerations nor bibliographies. It constitutes a review of the whole subject put together in tabular form, so arranged as to make the information contained therein easily accessible. The initial chapter gives a description of the apparatus required by those investigating diseases of the tract. This is followed by a review of its anatomy from the point of view of its practical application. The physiological and pathological characters of urines, with special reference to the estimation of renal function, are considered in detail, also the uses of the cystoscope. The rest of the book is given up to the description of the various diseases affecting the genito-urinary tract. The schematic arrangement of the book is admirable. The illustrations, which are all diagrammatic, are original and demonstrate very clearly the subject matter of the text. This type of work is valuable to a busy practitioner and should be much appreciated.

FIRST-AID IN EMERGENCIES.

Third edition. By ELDRIDGE L. ELIASON, M.D. London and Philadelphia: J. B. Lippincott Company. 1920. Pp. 233. 7*s.* 6*d.*

THIS book has reached its third edition, so we presume that it has been found useful. Books on first-aid are very numerous and of varying excellence, and the one now before us is, to our mind, not one of the best. Some of it is good, but the work is unequal. Thus most of the first chapter, entitled General Considerations, is sound and clear, but in the section on "Carriage" the account of what Dr. Eliason calls "Across the Back Carriage"—i.e., what is called in this country "The Fireman's Lift"—is obscure, and no mention is made of the necessary modifications according to whether the patient is a man or a woman. In the section on bandaging the directions for rolling a bandage are singularly obscure and, we should have thought, quite unnecessary. The chapter on wounds is decidedly good. In the section on bee- and wasp-stings the author says that the poison is acid. This is true as regards the bee-sting only, that of the wasp is alkaline. No mention is made of the fact that some persons are very susceptible to either bee or wasp poison and may after a sting in any part of the body exhibit symptoms very like those of snake poisoning. In the chapter on fractures and dislocations it is stated rightly that when no doctor is available the renderer of first-aid may try to reduce a dislocation, but we cannot agree that in dislocation of the shoulder he should try the old-fashioned plan of pulling on the arm with his foot in the axilla. Manipulation, which he should have been taught, is far safer. On p. 166 a warning ought to have been given against the use of emetics if there is any suspicion of a caustic acid or alkali having been swallowed.

A POCKET MEDICAL DICTIONARY.

Giving the Pronunciation and Definition of the Principal Words Used in Medicine and the Collateral Sciences. Eighth edition, revised. By G. M. GOULD. A.M., M.D. London: H. K. Lewis and Co., Ltd. 1920. Pp. 1016. 9*s*. net.

"Pocket Gould," in its eighth edition, contains 40,000 words, and although it has been carefully kept up to date in all important respects, its size has not perceptibly increased and the book can still be carried in a fairly capacious pocket. Pronunciation and definition are given of the principal words used in medicine and the collateral sciences, and useful tables are added of the arteries, bones, muscles, nerves, and various groups of micro-organisms. In an appendix is a physician's dose table in both apothecary's and metric system, based upon the ninth revision of the U.S. Pharmacopœia.

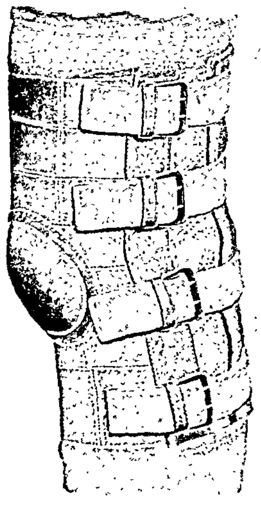
JOURNALS.

Hereditas.—The strong and growing tendency of modern science to hark back to connubial indiscretions in the ancestors of the present stock in order to explain some of its worst faults is reflected in the promotion of a new journal, *Hereditas*. Its first number has already been issued under the auspices of the Mendelian Society in Lund, Sweden. The international character of this journal is assured by the contributions being written in English; French, or German. The contents of the first number include a paper by H. Lundborg on Hereditary Transmission of Genotypical Deaf-Mutism, a paper by Nils Heribert-Nilsson on Zuwachsgeschwindigkeit der Pollenschläuche und gestörte Mendelzahlen bei Oenothera Lamarckiana, and another by Hans Tedin on the Inheritance of Flower Colour in Pisum. Emanuel Bergman contributes a paper on a Family with Hereditary (Genotypical) Tremor, and Hans Rasmuson a paper on Einige genetische Versuche mit Papaver Rhœas und Papaver Lævigatum. A. Akerman describes Spelt-like Bud-sports in Common Wheat, and J. Rasmusson discusses Mendelnde Chlorophyll-Faktoren bei Allium Cepa. Altogether an interesting assortment of papers by authors, some of whom are also well-known authorities. It must, however, be admitted that literary production with regard to the problems of heredity is apt to outrun writers' knowledge of this subject, with the result that they stand rebuked for their ignorance of the A, B, C, of the laws of heredity. Thus, in the present number, Dr. H. Lundborg takes his countryman, Dr. Ebbe Bergh, rather severely to task for his "insufficient knowledge of the laws of heredity." An interesting conclusion to which Lundborg comes in his paper on deaf-mutism is this: that, contrary to older views, acquired deaf-mutism is far more common than inherited deaf-mutism. Meningitis and scarlet fever are, in his opinion, the most frequent causes of the former. The editors of this new undertaking are to be congratulated on their promising start, and if the interest of succeeding numbers is maintained by an equally high standard of contributions, the subscription of 25 Swedish crowns for each volume of about 350 pages is a sound investment to all interested in this subject. The editor's address is Adelgatan 7, Lund, Sweden.

British Journal of Children's Diseases. Vol. XVII. October-December, 1920. Edited by J. D. ROLLESTON, M.D.—In a paper entitled "Pædiatro-Mathematics or the Application of the Principles of Mathematics (and Physical Chemistry) to the Study of Child Physiology and Pathology," Dr. W. M. Feldman deals with some of the quantitative researches that have been carried out in the human infant, including researches on infant mensuration, the law of minimal surface area, Guldberg and Waage's law of mass action, the application of optical methods, the application of electrical methods, and the principles of mechanics.—In the concluding part of his paper on Stigmata of Predisposition to Bone and Joint Tuberculosis Mr. W. C. Rivers discusses nasal defect, which includes ozæna, catarrhal rhinitis and their combination, hypertrichosis and squint. It was found that in bone and joint tubercle these non-tuberculous nasal abnormalities were more than three times as common as in the general population. Hypertrichosis was found in 3 out of 130 boys and in 3 out of 116 girls examined at the Treloar Hospital at Alton as compared with 0·5 per cent. among 181 normal schoolboys. Squint, on the other hand, occurred in only 0·5 per cent. of 350 children with bone and joint tuberculosis, whereas the normal occurrence is about 2 per cent.—Dr. Edmund Cautley reports a case of Congenital Pulmonary Regurgitation (Transposition of the Spleen) in a female infant aged 2 months, admitted to hospital for cyanosis and dyspnœa, some degree of which had been present since birth. The necropsy showed that both the right auricle and ventricle were relatively much hypertrophied and somewhat dilated, while the left auricle and ventricle were unduly small in proportion to the size of the child and still more so in proportion to that of the right side of the heart. The pulmonary artery and orifice were much larger than normal. The spleen was small and congested and situated between the right lobe of the liver and the diaphragm, together with many pea-like accessory spleens.—In his Brief Considerations on Surgical Tuberculosis in Infants, Dr. Charles Greene Cumston, of Geneva, discusses mesenteric adenopathy and tuberculous peritonitis, subcutaneous abscess, subcutaneous gummata, tuberculosis of the lymphatic glands, tuberculous infection of the epididymis and testicles, bone and joint tuberculosis, and tuberculous rickets.—Dr. Maxwell Telling reports a case of Primary Sarcoma of the Small Intestine Causing Unusual Symptoms in a boy aged 3½ years, successfully removed by laparotomy.—Dr. Hugh Ashby writes on Œsophageal Obstruction in Young Children, which he thinks is primarily spasmodic in origin and later becomes fibrous, as in hypertrophic stenosis of the pylorus.—Dr. D. H. Paterson reports a case of Transmitted Congenital Syphilis. The patient was a boy, aged 2½, with the characteristic facies of congenital syphilis and mentally deficient. The Wassermann reaction was positive. The mother also showed the characteristic features of congenital syphilis, and her Wassermann reaction was +++. The father's reaction was negative. The mother's mother had died of tabes, so that the disease had apparently been transmitted from the maternal grandmother to her daughter, who had given birth to a syphilitic child. The possibility of the mother having become reinfected prior to the child's birth had been considered, but there was no reason to believe that this was the case.—The abstracts from current literature are devoted to surgery and ophthalmology.

New Inventions.

AN IMPROVED KNEE-CAP.



A PERFECTLY fitting knee-cap—i.e., one which closely embraces the joint in all positions of flexion as well as in full extension—is probably unattainable, but it has seemed to me that it might be possible to improve upon the types usually supplied. The usual form with eyelets and laces proving unsatisfactory, some years ago, on the suggestion of a patient, I substituted straps and buckles, and the knee-cap shown in the figure was evolved. It is made in high-grade stout drill and best quality elastic web, so fitted in strands overlapping one another as to prevent any bulging on bending the knee, which would happen if the elastic were in one piece. A soft pad is placed over the front of the patella as an extra protection, while the back of the knee-piece is cut out to allow free flexion. The adjustment being made by the webbing straps allows of more or less pressure being applied at any particular point that may be necessary.

The appliance has been made for me by Mr. Albert Edward Evans, of 38, Fitzroy-street, London, W., who has most successfully carried out and improved upon my suggestions.

Marble Arch, W. E. MUIRHEAD LITTLE, F.R.C.S.Edg.

THE LANCET.

LONDON: SATURDAY, JANUARY 22, 1921.

The Question of Referred Pain.

No symptom leads with half as great frequency to the seeking of medical advice as pain in one or other form. Being essentially subjective, however, no symptom gives rise to greater difficulties in interpretation. There is a tale of a compensation-hunter who, on the threshold of the medical referee's consulting-room, received the last word of advice from his abetting friend: "Say you have pain in your back; he can't say you haven't." Compelled to derive his knowledge of the genuineness of the phenomenon from accompanying signs, if he has any reason to question the bona fides of the sufferer, the investigator is faced with theoretical as well as with practical difficulties when he pursues the matter further. Some would hold there is no such thing as a pain-sensation, that pain is an affective element accompanying sensation, as is pleasure, and can be differentiated into a tactile or temperature sensation on the one hand and a feeling of dys-pleasure on the other. Yet the apparently quite distinct peripheral physiological mechanism for the reception and conduction of pain impulses militates against the hypothesis. Assuming the similarity of pain to other sensations of the same order, we can understand that for its conscious appreciation an integrated nervous system and a degree of attention are requisite, and that with the appearance of the sensation in consciousness the matter of its localisation also arises inevitably. Only when consciousness is in partial abeyance is localisation, as it were, dissociated; a patient in the semiconscious state following a stroke will often indicate by a general restlessness, a diffuse motor reaction, that a painful stimulus applied to the skin is reaching his sensorium, and by the same token will show that he cannot place its origin. Ordinarily, a nociceptive excitant of a physical order sets going an impulse through a neural chain which at the cortical level (it is immaterial in this connexion whether the metamorphosis from physiological to psychical is thalamic or cortical) becomes pain, and at the same time consciousness says the pain "comes from" such and such a spot. All painful sensations, of whatever quality or intensity, are thus "referred," and the use of the term "referred pain" in a restricted sense is undeniably responsible for some confusion of thought. Correct reference of painful stimuli in the wide sense is simply a question of the application of the trial-and-error process, and the behaviourist might tell us some time at what day after birth the infant will correctly localise the offending pin. Throughout life, doubtless, accuracy of localisation varies with the individual. Under pathological conditions, moreover, pain of central derivation is well known to occur, as with certain kinds of lesion in, and in the immediate vicinity of, the optic thalamus, and, it may be, of the cord too; and these central pains are "referred" to some point or points on the somatic periphery: but most practitioners of neurology have had clinical experience of topoalgias and psychogenic pains due to a "lesion" in the psychical sphere, yet these "central" pains likewise are placed somewhere on an outer circuit.

Descending to a physiological level, but taking with us the fundamental fact that pain does not exist as such except in consciousness, we find a considerable number of varieties of pain-reference, among which it might be possible to introduce some order by an attempt at classification. Pain, for example, is sometimes felt in the ear with or after toothache, and neuralgia of the middle division or whole area of the trigeminal not uncommonly accompanies disease of the antrum; unilateral glossodynia may be a symptom of an impacted wisdom tooth. Pain thus excited in one branch of a peripheral nerve system from irritation in another branch might, as BEHAN suggests, be called "associated" pain, though the term is perhaps more usually employed in connexion with pain in organs physiologically associated though innervated by different anatomical nerve-groups—e.g., the breast and the uterus. When it is referred to a different peripheral distribution via the spinal cord or its analogue pain may be regarded as "transferred"—for example, the occipital pain of some forms of nasal disorder. The pain of irritation of a nerve trunk or root, or root ganglion, is not placed locally but is "referred" in an upward or downward or outward direction, as with the lightning and girdle pains of tabes, the pains of peripheral neuritis, of causalgia following wounds, pain connected with psoas abscess, and so on; and to this ordinary occurrence the term "referred pain" should perhaps be confined. The reference of pain by the cortex to the foot, say, and not to the posterior root ganglion concerned, is in reality a misreference. "Sympathetic" pain is observed when there is pain both in the part affected and elsewhere, as, for example, in severe facial neuralgia, when pain may appear also in neck and shoulder; the occasional simultaneous pain in heart region and left arm in angina is somewhat different. The pain in a phantom limb after amputation, or the anæsthesia dolorosa of some forms of advancing spinal disease, is a "projected" pain, being localised or projected either to a part that is wanting or to an area in reality anæsthetic, yet there is little to be gained by the use of the term, since, as a fact, all pain is "projected," if we remember its cortical source. Much controversy has raged round the question of referred in the sense of "reflex" or "reflected" pain from one sensory system to another—that is, its transference or deflection from viscero-sensory to somatic-sensory system. Half a century ago HILTON discussed, in his classic "Lectures on Rest and Pain," the origin of the "sympathetic pain" which he noted was referred to the surface of the body in disorders of viscera not necessarily immediately underlying. J. ROSS, too, who devoted much study to the subject, followed HILTON in supposing this somatic or cutaneous reference was due to a central connexion of viscero-sensory with somatic-sensory nerves; he was of the opinion that both "splanchnic" (visceral) and somatic (cutaneous) pain might exist in visceral disease. With the names of Sir JAMES MACKENZIE and of Dr. HENRY HEAD further research on the subject in England is chiefly associated; the former came to the conclusion that the abdominal viscera were completely insensitive, as have a number of surgeons and other investigators since then, the origin of the pain produced by certain forms of handling being situated in the end-organs mainly of parietal subperitoneal tissue. HEAD, however, considered that the viscera are endowed with "deep and protopathic sensibility in a low degree," and that when a painful stimulus is applied to a part of low sensibility, in close central connexion with a part of much greater sensibility, the pain is felt in the latter rather than in the former, to which the stimulus is actually applied. Recent research has not here been wholly confirmatory. In his Goulstonian lectures (1911) Dr. A. F. HURST confirmed the views of Ross that disease of the alimentary canal may cause true visceral pain, which is often present alone, but may be associated with pain referred to the skin connected with the same spinal segments. He pointed out that MACKENZIE did not take into consideration the fact that a nerve-ending may be sensitive to one form of stimulation—the adequate stimulus—but insensitive to all others, and that cutting, pricking, and pinching of viscera are not stimuli occurring under natural conditions; and he demonstrated tension to be the adequate cause of true visceral pain. Professor C. S. SHERRINGTON, too, has stated that the receptors of the intero-ceptive field, as he calls it (as opposed to the extero-ceptive or external-surface field), will always respond to the adequate stimulus, which must be of a certain kind; "if mechanical stimulation resembles that occurring in the natural accidents that concern medicine, the experimental results fall into line with those observed at the bedside."

The conclusion, therefore, is that the popular belief in actual visceral pain is supported by physiological research, and that reflex, reflected, or, better still, deflected pain is far from being the common accompaniment of abdominal disease it is uncritically taken to be. In his recent Croonian lectures HURST mentions that his first doubts on the reliability of the somatic-sensory signs of visceral disease arose when he had the opportunity of examining ten cases of gastric ulcer operated on by Sir BERKELEY MOYNIHAN. In every case he failed, on the day before operation, to find any cutaneous hyperæsthesia, yet the ulcer was demonstrated in nine out of the ten on the operating table. He concludes that "referred" pain in abdominal disease is so rare as to be of no diagnostic value, with the possible exception, in his experience, of its occurrence in conditions leading to distension of the pelvis of the kidney. Since the extero-ceptive field far exceeds the intero-ceptive in its wealth of receptors we can well understand the comparative poverty of visceral sensations, even in disease, and the tendency of the brain to misinterpret or misrefer an unusual or rare sensation. We do not, however, know under what conditions this occasional misreference from visceral disease occurs, nor are certain peculiarities it exhibits fully understood; MACKENZIE himself has pointed out that the areas seldom, if ever, correspond to the full distribution of a spinal segment, or segments, and are ill-defined and often overlap. In view of the fact that pain, of whatever origin, is "projected" by the cortex in the various ways and following the various physiological mechanisms mentioned above, the specificity and practical importance of the viscero-somatic transference of pain cannot be regarded as firmly established.

Reciprocity in Medicine.

A EUROPEAN Commission was invited last summer to attend a session of the American Medical Association, the Commission consisting of representatives of the English Royal Colleges —Sir HUMPHRY ROLLESTON and Mr. H. J. WARING; of the triple Examining Board of Scotland—Dr. NORMAN WALKER; and of the University of Paris—Professor G. ROUSSY and Professor E. E. DESMAREST. The reference of the Commission was, to be present at the examinations of the newly instituted National Board of Medical Examiners of the United States, and to visit a group of recognised centres of professional education, and thus familiarise itself with the machinery of medical training in the United States as a whole. The Commission was received on the other side of the Atlantic with great cordiality, when every facility was given for full comprehension of the conditions. Report has been made to the General Medical Council by Sir HUMPHRY ROLLESTON and Mr. WARING, and to the Royal Colleges of Edinburgh and the Faculty of Physicians and Surgeons of Glasgow by Dr. WALKER, so that both documents are now public. Dr. WALKER'S report, with its interesting commentary, appears in full in the January issue of the *Edinburgh Medical Journal.*

The reports between them give an exhaustive picture of medical education as it now is in the United States, and show also various recent steps, some only just taken, for improvement of the curriculum. As was necessary in a rapidly evolving country, medical education in the United States until the beginning of this generation was somewhat chaotic. It was impossible for the newer States of the Union to start with a complete and perfect system of medical education when they had all the claims of a growing civilisation pressing upon them; and in the newer universities and institutions of the younger States the curriculum provided, while it was as good as could be expected, was greatly inferior to that which prevailed in the great centres of the New World, where the standard was as high as anywhere in the old. A practical step was taken in 1892, when a higher national standard was shown by the establishment of State Medical Boards, which abolished many institutions for students, finding them little more than private enterprises for the sale of degrees and diplomas. Then the American Medical Association, recognising the need for an adequate general pattern of training, if the doctors in one State were to be allowed to practise without question in any other—to say nothing of the acceptance of American practitioners by other countries on a reciprocity principle—graded all the American medical schools into three classes, A, B, and C, and, by adversely reporting on the conduct of those falling under B and C, led to the extinction of many of them. The process of destruction was indicated in a review of American medical education recently published in our columns.[1] There had been 439 medical schools existing and extinct in the United States, but in 1906 there remained only 162 medical colleges, and by 1920 the number had fallen to 86, and, while a few of these would receive no recognition in Great Britain, 70 are graded in class A. On this work the American Medical Association must be warmly congratulated. The next great step was taken in 1915, the object being to collect the movement centrally which had been growing peripherally under the separate State Medical Boards, and to ensure that the holders of national licence should be able to practise in all the States of the Union, accepting the certificate of a National Board of Examiners. Twenty States have now given adherence to this scheme, which owes its origin to Dr. W. L. RODMAN. A Board of 18 members has been constituted, on which sit representatives of the Army, Navy, and the public health services, of the State Medical Boards, and of the medical profession generally; two laymen also find seats on the Board, having been appointed for their knowledge of medical education and organisation. The National Board is for the present financed by the Carnegie Fund for the Advancement of Learning, whose president, Mr. H. S. PRITCHETT, is one of the lay members.

---

[1] THE LANCET, 1920, ii., 667.

By consent among civilised nations medicine is an international affair, and the view is universal that common action should be taken to eliminate epidemics, to increase the world's stock of information, and to promote general public health. This is only another way of commending an ideal, whose value none will deny, that medical services should be international, and so organised that a qualified doctor of one country shall be at liberty to practise with due status in any other country. It is very satisfactory to learn from both these reports that the examinations conducted by the National Board of Examiners in Washington have so impressed the British members of the European Commission as to earn the recommendation that American practitioners holding the certificate of the Board should be admitted to our final examinations without further question. This, of course, is but a limited reciprocity, but to those who remember what medical education in the United States was 30 years ago it will come as a wonderful proof of the progress made. The reasons for the recommendations are set out in both reports with great particularity, different points being taken up, while a common message is delivered. We feel that these reports should be in the hands not only of the General Medical Council and of the various corporations directly represented on the Commission, but of all who take a personal interest in medical education.

◆

Chronic Farcy.

DURING the last six years, amongst the soldiers returned from active service, various types of ulceration of the skin and mucous membranes have been observed, commencing with some definite inflammation of the superficial or deeper tissues and the formation of bullæ, papules, and pustules; evacuation of the contents of these formations succeeds, and local extension of the eroded surface is followed by a more or less rapid and complete healing of the lesion. These were looked upon as having their origin in syphilis, but failure to obtain the Wassermann reaction often negatived this diagnosis. Glanders may, now and again, have been diagnosed, but, up to the present, few records appear to have been published, and it is certainly interesting to find that two of the few cases of glanders (or farcy) recorded—one[1] published by Colonel LEONARD S. DUDGEON, Major S. L. SYMONDS, and Captain WILKIN, working together in Salonica, and a second[2] by Dr. F. H. JACOB, Dr. HUBERT M. TURNBULL, Dr. JOSEPH A. ARKWRIGHT, and Dr. GERTRUDE M. DOBRASHIAN at Nottingham—both occurred in civil life. The patients appear to have been infected without coming into any sort of direct or intimate contact with horses or mules. In both the process was suspected to be of syphilitic origin, but in both the Wassermann reaction was negative. In the Salonica case Dr. DUDGEON had the advantage of the collaboration of a member of the Army Veterinary Service. In Dr. JACOB'S case it was unfortunate that the patient "attributed his complaint to infection from the diseased udder of a cow," for although this may be perfectly correct, cattle are said to be completely immune against glanders as regards spontaneous infection, and the statement was to that extent misleading, though it is known that localised ulceration, which rapidly heals, follows inoculation of these animals. Both cases ran a somewhat chronic course (there is no record of the death of the Salonica case, four months), the Nottingham case surviving for 13 or 14 months. These cases are of special interest in so far that the bacteriological and histological reports, in each case somewhat one-sided, are complementary to one another, Dr. DUDGEON'S case being studied very fully serologically and bacteriologically, Dr. JACOB'S case histologically. A point of interest is that the organism first isolated from Dr. DUDGEON'S case failed to produce the characteristic lesions of the testicle in the guinea-pig, whilst after passage through a mule a bacillus which had all the cultural and micro-chemical characters of the *Bacillus mallei* set up an acute septicæmia in the smaller animal. For the details of the blood immunity reactions the reader is referred to the original article, but it is of interest to note that the complement-fixation and agglutination reaction rise simultaneously, and that both attain their highest point just before the death of the animal. Unfortunately, in Dr. JACOB'S case no cultivation was made, but it may be accepted from Dr. TURNBULL'S report on the histological examination of the tissues submitted to him that changes, essentially those associated with glanders, were met with in the skin and lungs, those in the latter especially according well with the pneumonic processes reported by MCFADYEAN in his Harben lectures[3] for 1904. Dr. TURNBULL also describes with great care and much detail the bacteriæmia and the embolic character of the process, the necrosis and pus formation in the inflammatory centres, the karyorrhexis, the leucocytic infiltration, the increased number of mononuclear cells arising through the proliferation of the connective-tissue cells, with here and there the infiltration of the tissues with sero-fibrinous lymph. Here the nature of the process was scarcely realised until too late to obtain cultivations of the bacillus; this was specially unfortunate in view of the difficulty of staining the *B. mallei* in the tissues.

Dr. TURNBULL'S histological report is a model of its kind, and may well form a basis for the description of future cases of this type. Its value would, of course, have been enormously increased had it been possible to make a bacteriological and serological investigation of the case, and it is to be hoped that when opportunity occurs complete examinations corresponding to the two valuable contributions to our knowledge of the pathology of glanders made in these two cases may be carried out on a single case. In view of the manifestations of the disease here met with—a perivascular lymphatic and embolic infection—it might, perhaps, be well to speak of the condition described as chronic farcy. It is interesting to note that of 21 chronic cases of farcy in man recorded by HOWARD BENDALL as early as 1882, 15 recovered or were partially cured, the six that died succumbing in periods between 50 days and 14 months. In one of those that recovered the disease lasted as long as 2½ years. A disconcerting feature about the Nottingham case, but one that in future must be borne in mind, is that the tissues of the udder of a milch cow may become the temporary nidus of the *B mallei* and that a condition of mild chronic farcy may there be set up from which the milker may become infected. It then becomes possible for a glanders infection to be contracted by those who partake of the milk, even though in its passage through the bovine carrier host the organism has become greatly attenuated in virulence. The mild disease process thus set up may through its very modification be difficult of diagnosis, and yet from this mild infection centre a much more virulent type may be developed by passage.

Annotations.

"Ne quid nimis."

CARBON MONOXIDE IN COAL-GAS.

CARBON monoxide has been described by Brouardel as holding first place amongst the toxic gases—he was speaking of accidental poisoning and not of the deliberate use of respiratory noxæ; and the Registrar-General attributes 704 deaths in 1919 to the absorption of deleterious gases. It is, therefore, not merely a question of fuel value what proportion of carbon monoxide should be contained in the coal-gas supplied to us; it is a matter on which medicine is entitled to raise its voice. The number of cases in which coal-gas has been employed for suicidal purpose have shown some signs of increasing lately; such acute poisoning would be difficult in any case to prevent, but it is well known that carbon monoxide, by its peculiar power of monopolising hæmoglobin, is a cumulative poison, and it is important to limit its possibilities of harm. The question of the post-war basis upon which gas shall be sold, as well as the standard of quality to be applied to it, have both been the subject of considerable inquiry and discussion. The matter originated within the gas industry itself during the war, when it was found that the total yield of gas from a ton of coal could be greatly increased by combining the usual process of carbonising in retorts with the simultaneous production of water-gas by passing super-heated steam over the incandescent coke. Unfortunately, the resulting mixture of coal- and water-gas is not only of considerably lower heating power (a matter which can be adjusted by grading the price) but also contains much more of the poisonous carbon monoxide. The whole subject was taken up and reported upon by the Fuel Research Board; and, finally, the British Association Fuel Economy Committee, of which Professor W. A. Bone, F.R.S., is chairman, considered it and made certain recommendations. One of these recommendations was that in no circumstances should it be permissible for a public gas undertaking to supply to its consumers a product containing more than 20 per cent. of carbon monoxide. This recommendation was in harmony with the findings of a Home Office inquiry held in 1899, at which Dr. J. S. Haldane took part. It was then agreed that, in view of the imperfect state of the fittings in the poorer houses of urban districts, the only effective method of preventing danger from leakage was to fix a limit which the carbon monoxide should not exceed. When the Gas Regulation Act, 1920, became law last July the Board of Trade was instructed to hold a special public inquiry into the question, and a committee, consisting of Sir William Pearce, M.P. (chairman), Dr. T. Carnwath, Mr. William Doig Gibb, and Mr. T. Gray, D.Sc., will proceed in the immediate future to take evidence with a view to arriving at a decision which, under the provisions of the Act, will have statutory effect. In view of the importance of the decision from the hygienic standpoint, we trust that this committee will give due weight to the need of limiting the carbon monoxide proportion. Health must come first in such a matter, and due consideration for health will prove in the long run to be justified economically.

VOLUNTARY HOSPITAL FINANCE: A LAY COMMITTEE.

IT will be remembered that when the Ministry of Health (Miscellaneous Provisions) Bill was before Standing Committee a debate ensued over Clause 11, which was intended to regularise the taking over or founding of general hospitals by municipalities. It was, and is, an obvious responsibility of the Ministry of Health to further a general scheme for the country under which all classes of the population may obtain the benefits which can only follow upon institutional treatment, but the particular clause of the Bill was challenged from so many directions that Dr. Addison withdrew its criticised portion and offered to appoint forthwith a Committee "to inquire into and report upon the financial position of the voluntary hospitals throughout the country," adding that the Committee would consist of five members only, none of them being medical men or connected with hospital arrangements in any way. The Committee has now been constituted as follows: Viscount Cave (Chairman), Sir Clarendon Hyde, Mr. R. C. Norman, and Mr. Vernon Hartshorn. A fifth member, who will be a representative for Scotland, remains for appointment, while it has also been decided to include a chartered accountant of high standing, a very welcome addition.

HEREDITY IN CONGENITAL HIP DISLOCATION.

IN a recent bulletin of the Paris Academy of Medicine[1] L. Dubreuil-Chambardel discusses the hereditary factor in the incidence of congenital dislocation of the hip, and traces the later histories of five cases operated upon for this deformity. Judging by this and two previous papers by the same author, heredity is evidently regarded by him as playing a larger part in the production of this deformity than most surgeons would be ready to admit. Tubby[2] certainly says "heredity is a marked feature" in this deformity, and he quotes Marath[3] as finding a history of heredity in 40 per cent. of his cases and Vogel[4] in 30 per cent. of his. On the other hand, Whitman[5] says "hereditary influence can be established in a few instances" only, while Bradford and Lovett[6] and Taylor[7] would seem to agree with him. H. A. T. Fairbank found signs of hereditary influence in only 8 of 200 cases. It is probable that more extensive investigation into the family histories of these cases would have added to this figure, but the percentage could not have approached those given by Vogel and Marath. There does not appear to be any reason for regarding congenital dislocation of the hip as being the result of hereditary influences to a greater extent than other congenital deformities. In all we find an occasional case giving a history of the same or other congenital deformities affecting other members of the family, but this is the exception and not the rule. In the case of congenital deformities of the hand A. Steindler, in a series recently published, traced an hereditary factor in only 20 per cent. The five cases detailed by Dubreuil-Chambardel tend to show that reduction of the dislocation has no influence whatsoever on the incidence of the deformity in the offspring of the cases so treated. Treatment of a condition which is, at most, only the result of an inherited tendency, could hardly be expected to influence the possible transmission of that tendency.

EDUCATION AND DEMENTIA PRÆCOX.

Dr. Deroitte, of Brussels, when on a visit recently in this country had the opportunity of comparing British asylums with those in his own country. He was greatly struck by the comparative rarity of dementia præcox in our institutions, and, casting about for an explanation, has hit upon the English educational system as the secret of our "solid nervous systems, the emotions always reined in by an ever-calm judgment." In *Le Scalpel* for Jan. 1st he devotes ten pages to a comparison of the English and Belgian methods of secondary education and an exposition of the wearing effect of the latter upon Belgian nerves. Long hours of monotonous work in school, work taken home in the evening (a thoroughly reprehensible system!) and, "sad to relate," long written punishments as well, all help to wear out the overtaxed brain. Corporal punishment is too violent and is one of the causes of mental shock. The English system avoids this danger by relegating punishment to a monitor or at least assuring that it is not administered by the same master who has cause for annoyance. Instead of punishing a boy for laziness he should be made to feel the sense of responsibility for his own mental and physical development. Dr. Deroitte quite rightly lays emphasis on the possibility of psychic shock through the careless exposure of sexual vices and their danger at the susceptible age of puberty. Public addresses on these subjects he condemns categorically. Strangely enough, he omits to mention that a child who has been properly educated in the years before puberty is not liable to shock from the discovery of his own sex mechanism. The practical deductions of this study are two: in school, the development of spontaneity, the exercise of the will, the culture of self-confidence; out of school, the encouragement of physical exercise and of hobbies.

THE CIRCULATORY FAILURE OF DIPHTHERIA.

THERE are a dozen ways in which the heart can be brought to admit defeat at the hand of disease, yet in the last resort it is true that all these diverse processes kill by the effect they produce on the metabolism of the myocardiac cell. In a recent elaborate study of circulatory failure in diphtheria Dr. Esther Harding[1] suggested a similar wealth of processes busy at the task of killing the patient and an ultimate convergence of all those processes on the one point of interfering with the peripheral circulation in such a way that the vital tissues, and particularly those of the brain, are no longer able to maintain their metabolic balance. According to Dr. Harding, whose studies were carried out in 1918 at the Plaistow Fever Hospital, neither myocardial degeneration, profound though it is in diphtheria, nor vascular relaxation, is sufficient to account for that failure of the circulation which is the lethal factor in diphtheria. She is impressed by a faint general œdema which is present early in diphtheria, to which she gives the name of "lymph-logging." This is accompanied by a rise in the specific gravity of the peripheral blood, and is ascribed by her to altered osmotic conditions and increased permeability of the capillary walls. A state of oligæmia, or shortage of blood in circulation (comparable to that observed in surgical and other forms of shock), is thus induced early in diphtheria, and is aggravated later in the disease by diminution in the cardiac output and by vascular relaxation. Each of these latter phenomena is traceable to a number of sources, which are examined carefully by Dr. Harding in an argument demanding close attention. Her tentative conclusions as to the actual nature and correct treatment of the circulatory failure have recently received support from experimental researches which she has been carrying out in the department of biochemistry and pharmacology in the National Institute for Medical Research at Hampstead. The condition has been found to resemble the experimental "shock" produced by histamine. In the words of the annual report of the *Medical Research Council*, "evidence has already been obtained pointing clearly to the possibility of saving life by symptomatic treatment of the circulatory condition in cases in which specific treatment by the antitoxin alone is of no avail." It is to be hoped that the clinical testing of these ideas, which is promised in the report, will confirm these anticipations, for it is possible that if so we shall be furnished with new means of saving life, not only in diphtheria, but also in other forms of infective disease.

RECENT RESEARCHES ON PELLAGRA IN EGYPT.

WITH surrender of the defeated Turkish Army in Palestine and arrival in Egypt of many thousands of prisoners of war for internment, unexpectedly favourable opportunities became available in 1918 to British Army medical officers for investigating pellagra. It may be mentioned that from their arrival in Egypt up to the end of 1919 there occurred among 105,668 Turkish prisoners some 9257 recognised cases of pellagra, but there were probably many other undiagnosed instances. A committee of investigation was appointed in 1918 by the Army Medical Department, consisting of Colonel F. D. Boyd, A.M.S., and Lieutenant-Colonel P. S. Lelean, R.A.M.C., with whom were associated a number of experts of various kinds. In their report, on which we commented in THE LANCET of Sept. 13th, 1919, it is stated that no ætiological relationship of the malady to bacteria, protozoa, or to blood conditions had been discovered, and that as regards food there was so constant an association between the biological value of diet and the occurrence of pellagra, they considered the lack of sufficient biological value of protein stood in ætiological relationship to pellagra, certainly as an exciting factor, and possibly as the determining factor.

As some uncertainty existed on several points connected with the disease another committee was appointed[1] by the Army Medical Department early in 1920, consisting of Major A. C. Hammond-Searle, R.A.M.C., and Captain A. G. Stevenson, R.A.M.C., with Lieutenant-Colonel P. J. Marett, R.A.M.C., as bacteriologist. The Committee began work in the spring of 1920, and their report, now issued, bears the date of Sept. 15th of that year. Some of the matters which were investigated could not be completed owing to the rapid repatriation of the Turkish prisoners during 1920, and the consequent disappearance of much of the material on which the inquiry was being carried out. One of the conclusions arrived at was that all the ætiological factors in pellagra are not to be explained solely on the theory of deficiency of protein of high biological value, and that therefore pellagra cannot be regarded in itself as a true "deficiency disease." There was evidence that an unhealthy or ulcerated intestinal mucous membrane becomes infected by anaerobes, with their resulting growth and toxic action. In post-mortem examination of fatal pellagra cases the intestine showed ulceration in a large percentage of them; the mucous membrane of the small intestine almost invariably showed denudation with, in certain instances, superficial ulcers, the pigmentation of which was a feature. Cultures, from fæces of definite pellagra patients and from the small intestine of post-mortem cases, were taken by Colonel Marett under anaerobic conditions after elimination of the ordinary intestinal organisms. In over 90 per cent. of cases organisms were grown that were morphologically indistinguishable from *B. welchii*, and in 85 per cent. of cases terminal or subterminal spore-bearing organisms were isolated. On the other hand, stools from healthy Turks similarly treated did not show the presence of anaerobes. Samples of maize and maize-flour, obtained from an endemic pellagra area in Egypt and examined for organisms, also showed the presence of anaerobic spore-bearers. This high percentage of infection by anaerobes in pellagra cases, and the knowledge that these organisms flourish on dead tissues, is highly suggestive, to the Committee, of causal relation, as also the presence of anaerobes in samples of maize. To assist in obtaining proofs of this relationship attempts were made to induce ulceration in the intestine of dogs by means of dysenteric strains, and it was intended to follow up this by the introduction of anaerobic infections. Up to the date of the report, however, the experiments with the dogs were unsuccessful, so that the action of these organisms still remains undetermined. There was no evidence that suprarenal insufficiency was a factor in pellagra. In the opinion of the Committee the disease develops, first, as the result of lack of suitable or sufficient diet, causing lowered powers of resistance against infection by disturbing the maintenance of the healthy and protective activity of the intestinal mucosa; secondly, possible intestinal disease, such as dysentery or helminthiasis, causing ulceration and "malaction" of the mucous membrane, and consequent malassimilation; thirdly, infection of the weakened or ulcerated gut by anaerobes, and ultimate development of the symptoms distinctive of pellagra. As regards seasonal variation of the disease there are three reasons suggested: (1) the infection by anaerobes occurs coincidently with the season of greatest activity of flies, which are the probable carriers; (2) the optimum temperature for growth of micro-organisms is in the spring and autumn months, with possibility of resultant intercurrent infections; and (3) lowered resistance, due to possibly insufficient diet, this being most probable after the winter months.

---

[1] The Circulatory Failure of Diphtheria. By M. Esther Harding, M.D. University of London Press, Ltd. 1920. Pp. 176. 10s. 6d.

[1] Report on Investigations of Pellagra among Turkish Prisoners of War in Egypt in 1920. Pp. 65. With numerous charts and tables. Published at Alexandria. (Not on sale.)

The Committee state that although, "in a way, pellagra may be reckoned as a deficiency disease, yet the key to the deficiency is the amount and nature of the protein absorbed and metabolised; there need be no great divergence of views if it be recognised that an intestine, already damaged by previous ulceration, the presence of helminths *or some other cause*, is a priori incapable of the same degree of assimilation as a normal one." It will be conceded by most persons that under such circumstances toxins will almost certainly be absorbed from the intestines. In an addendum written after completion of the report the Committee give some interesting details of three pellagra cases which developed in August, 1920, among a batch of Turkish prisoners that had arrived from India and Mesopotamia about two months previously. One of these patients had been interned in India for five years and each of the other two for three years, during which period they had lived on a far inferior diet to that which they received in Egypt. Notwithstanding this better diet, the men developed pellagra in from two to three months after their arrival in an Egyptian endemic area of the disease. In the opinion of the Committee these facts point to some additional factor other than diet as the primary cause of pellagra; moreover, examination of the patients' stools showed, generally speaking, a similar infection to that already described in the previous pellagra cases. The histories of the three cases, it is suggested, bear out the theory, already mentioned, of anaerobic infection of the intestinal tract as the primary cause of pellagra. Had space permitted we could have drawn attention to the experimental and other work given in this interesting report. The findings of the Committee, it has to be admitted, are hardly in accord with the results obtained by other workers, and especially in the United States by Goldberger and Wheeler in their carefully planned and patiently carried out human experiments on volunteers in a Mississippi penitentiary, where all possible factors save diet seemed to have been excluded. The American experts have suggested that pellagra, as conventionally defined, probably includes at least two commonly associated but ætiologically and essentially distinct syndromes. It is possible that the group of symptoms, called pellagra, may originate from more causes than one. Recently Professor Gowland Hopkins[2] reminded us that the evidence pointing to an infection or toxic origin of pellagra had of late become weak, while that pointing to a dependence on diet had become strong. It is obvious that the ætiology of pellagra cannot be regarded as definitely settled. There is still room for the research worker to give us his help, either by confirming the findings of this Committee, or on other lines.

DENTAL DECAY.

THE cause, effect, and treatment of dental decay are dealt with at length in the annual report for 1919 of the chief medical officer of the Board of Education. The policy of the Board in taking a broad view of treatment and allowing each education authority to work out its own scheme gives an additional interest to the work, and makes for efficiency and good results. Obviously, a scheme suitable for an urban district is not necessarily the most suitable for a rural district, nor is that of a populous rural district necessarily the one for the scattered villages of a mountainous county. It is interesting to see how different authorities have tackled the problem. Various methods have been resorted to. The work has been done by private dental practitioners, dental hospitals, school dental clinics, and itinerant dentists, employing caravans or adapting rural centres for the purpose. A general recommendation is that until a full scheme is in operation it is better to deal effectively with a small area than inadequately with a large one. The statement that at least 50 per cent. of the elementary school population is found to be suffering from some degree of dental defect does not arouse in us the surprise expected, and instead of being horrified at Dr. Hamer's reference to the "notable improvement" in the London schools, where 51·5 per cent. of the children are still suffering from dental defect, we cannot for the moment help sharing his satisfaction. After all, 51·5 per cent. compares very favourably with the 94·5 per cent. of Northumberland and the 98·15 per cent. of Northampton. There is no doubt that in London the problem has been tackled courageously and effectively. The first records of the teeth of London children in 1905 show 90 per cent. with caries, 70 per cent. of them to a serious extent. There are a great many more children leaving school with clean healthy mouths than there were, and there is a marked diminution in the amount of serious decay. This is the branch of medical inspection and treatment which is bringing more apparent and more lasting results than any other. Under the present encouraging policy of the Board, which points out that the earlier inspection and treatment take place the better, the dental work in the schools is well on the way to being a model for other countries to copy. The large number of infant welfare centres now in existence ought to have a marked influence in lowering the incidence of dental decay in the elementary schools, not only by virtue of the arrangements for dental treatment but by the educational efforts in the way of proper feeding and ante-natal hygiene. Following up is possible through the nursery school, which establishes the link between infant welfare centres and the elementary school. We endorse Sir George Newman's plea for closer coördination between the various bodies dealing with dental hygiene from infancy to adult life. He explores the cause and effect of dental disease very thoroughly. Emphasis is laid on the connexion between the character of food and dental decay. The character of food is important, not so much in its effect upon the chemical composition of the teeth, but in its tendency, in certain forms, to promote fermentation—the forerunner of decay. W. Hunter has shown in his observations at the London Fever Hospital that cleanliness in children's mouths is most important. Serious conditions such as the septic complications of scarlet fever are much commoner when oral sepsis is marked. A certain amount of hard food is necessary for its cleansing properties and its place in promoting mastication.

---

[2] THE LANCET, Jan. 1st, 1921.

The shortage of dentists in the United Kingdom has raised the question of the employment of dental dressers. Sir George Newman leaves the question an open one, with a bias in favour of their employment. The shortage has become an acute problem, due as it is in large measure to the success of the unqualified advertising dentist. The report deals energetically with the dangers of unqualified practice, and supports whole-heartedly the conclusions and recommendations arrived at by the Dentists Act Committee, which urges that steps should immediately be taken to safeguard the public, and incidentally the qualified dentist, from the unregistered practitioner. We hope that the suggestion in the report that a school dentist could "examine approximately 80 children in a normal school session of 2½ hours and record his findings" will not be taken literally. We cannot help feeling that the records of the latter half of the time would by their inaccuracies nullify the work of the first half. Surely the employment of dental dressers is indicated if only to cover the ground not requiring skilled work, leaving the dentist free to do the real work conscientiously and deliberately. The Board of Education is to be congratulated on its comprehensive and sound scheme for dealing with the problem of dental defect.

FRENCH OPHTHALMOLOGICAL ADVANCES.

A REVIEW of ophthalmology in France during the year 1920, from the pen of Professor F. Tarrien, ophthalmologist to the Hôpital Beaujon, occupies a large part of a recent issue of the *Paris Médical*. Examination of the anterior parts of the eye (cornea, iris, lens, and anterior layers of the vitreous) under high magnification (80 to 100 diameters) has been brought to a high state of perfection by means of the binocular microscope and the Nernst slit-lamp. Similar instruments are employed in Germany and have been there adapted for the examination of the fundus.[1] Monbrun and Gautrand have recorded four cases of double hemianopia with macular vision intact, in three of which binocular vision was retained. The post-mortem examinations went to confirm the view that the cortical centre for macular vision is situated at the most posterior end of the calcarine fissure. This is the conclusion also arrived at by Gordon Holmes.[2] Monbrun believes that in the majority of cases the whole macular field is represented in both occipital lobes. Gordon Holmes, on the other hand, maintains that the macular field has not a bilateral representation. A good deal has been written in France, as in this country, on the ocular symptoms of encephalitis lethargica. Mild cases are characterised by fleeting attacks of diplopia and of ptosis with somnolence, but there is only a difference of degree between mild cases and dangerous ones. The disease appears to be on the increase both in France and in Great Britain. A. Cantonnet believes that in some cases of tabes, with or without ataxia of the limbs, the eye-movements may be affected not only by paralysis of different muscles, but in rare cases by paralysis of associated movements—of convergence and of vertical or lateral movements of the two eyes, or by simple incoördination of eye-movements. An epitome of an article on the pathology and treatment of exophthalmic goitre is of sufficient interest to warrant a reference to the original.[3] Apropos of glaucoma, a thesis of Hélène Baute is quoted in support of Elliot's trephining operation. The danger of secondary infection is recognised as a possibility, but the conclusion is that it is the operation of choice for cases of simple chronic glaucoma with tension but without inflammatory symptoms. Many English operators would go further than this in its favour, while some, on the other hand, have abandoned it. The question of foreign bodies in the globe, which was very much to the fore during the war, still causes controversy. Rollet recommends that if a magnetisable foreign body is diagnosed by means of the giant magnet the next step should not be to extract it, but to perform an iridectomy, and to defer the extraction to a subsequent sitting, when the operation can be performed with greater ease and safety than if the iris were intact. The same difference of opinion as to the relative merits of the scleral and corneal routes for extraction exists in France as in this country.

OPERATIONS FOR THE REMOVAL OF TONSILS.

FOR many years the operation for the removal of tonsils was regularly performed with a guillotine, though before the introduction of this instrument surgeons operated by seizing the tonsil with forceps and cutting off the projecting portion with a curved probe-pointed bistoury. Some operators used the French Mathieu's guillotine, provided with prongs to lift the tonsil from its bed, but most surgeons in this country preferred the Mackenzie's "spade" guillotine. This was used with the handle directed to the same side as the tonsil which was being removed, and rarely succeeded in excising the entire tonsil. The amount of tonsil thus removed varied with its position and with the skill of the operator, but it is safe to say that, 20 years ago, the entire tonsil in its capsule was only occasionally and accidentally removed. Indeed, the anatomy text-books of that time do not describe the thin capsule proper which encloses the tonsil together with the so-called supra-tonsillar fossa. Within the next few years, however, surgeons with a large experience of these cases were recognising the bad results in many cases of leaving the deep part of the tonsil behind, and were endeavouring to assure a more thorough extirpation by improvements in technique, such as applying firmer pressure with the guillotine and carrying the shank of the instrument transversely across the mouth, and for certain cases were returning to and improving upon the method of removal by dissection. In 1909 G. E. Waugh, in a paper published in this journal,[1] strongly advocated removal by dissection in all cases, and unreservedly condemned the guillotine; but in the following year S. S. Whillis and F. C. Pybus[2] described their method of using the guillotine reversed, pushing the tonsil through the ring of the instrument with the forefinger of the other hand; and about the same time in America Greenfield Sluder[3] began to practise a similar method, using the angle of the jaw as a fulcrum to dislocate the tonsil through the guillotine. These methods have proved most successful, and a large number of practitioners have found that they can quickly learn to remove the ordinary tonsil entire with the guillotine by the manœuvre of Whillis and Pybus. Although on the continent partial removal, usually by "morcellement," is still the routine practice, in Great Britain and America it is almost unanimously agreed that tonsils which call for removal should be removed entire. Under these circumstances the best method for effecting this end still remains the subject of discussion; on a question, about which opinion has varied so greatly within the last few years, an occasional review of the matter helps to clear the air, and we believe that Mr. M. Vlasto, in the article which appears in this issue, presents the general consensus of opinion very fairly. "To make the punishment fit the crime" is a sound maxim in surgery, and a more serious operation should not be performed provided that a less serious one can be shown to produce as good a result. There is no doubt that some tonsils cannot be completely enucleated with the guillotine and that, whatever general principles are arrived at, there will always be room for individual judgment in particular cases. In this country these operations are usually performed under general anæsthesia, but it appears from the paper by Mr. W. Morris, which is also to be found in this number, that all adult cases are now operated on at the Mayo Clinic by dissection under local anæsthesia. His description of the technique there adopted will be useful to those who wish to try it here.

SUPPURATING MYOMA UTERI.

THE subject of suppuration in uterine fibroids is discussed by Dr. J. W. Nixon,[1] who reports a case in a woman, aged 20, suffering from gonorrhœal endometritis, which occurred in the surgical clinic of Dr. John B. Deaver at the Lankenau Hospital, Philadelphia. The rarity of this complication is shown by the fact that this was the first example of the kind among 1200 operations for uterine fibroids performed by that surgeon. It is true that some authorities estimate the frequency of suppuration in fibroids as high as 5 per cent. (A. Martin) or even 15 per cent. (Cullingworth), but Dr. Nixon attributes this to an inaccurate classification, which includes necrosis, gangrene, and other forms of degeneration. Although a fibroid may become infected at any time, infection is most likely to take place during the most active period of sexual life—namely, from the twenty-fifth to the forty-fifth year. The date of suppuration after the first appearance of the tumour varies from 2 years, as in Dr. Nixon's case, to 10, 20, or even 40 years. In order of frequency, the factors leading to infection of a fibroid are pregnancy, surgical and obstetrical trauma, direct extension of infection from endometritis in the interstitial variety, torsion of the pedicle, especially in the cases of the subserous fibroid, chemical irritation by ergot or other drugs intended to contract the uterus, and mechanical irritation by X rays and radium. There is no type of organism peculiar to suppurating fibroids, but Dr. Nixon's case is the first example on record in which gonococci have been found. The symptoms are not distinctive except that the pain, which has hitherto been dull and dragging, is likely to assume a stabbing character. In some cases there may be a rapid increase in size of the tumour, accompanied by local tenderness, fever, night sweats, and possibly a discharge of pus from the vagina. A high leucocytosis is also suggestive. The prognosis is grave owing to the complications liable to ensue as well as to the debilitated state of the patient at the time of the operation. The mortality has been variously estimated from 27 per cent. (Kelly and Cullen) to 70 per cent. (Berger). Early operation is essential, hysterectomy, total or subtotal, being indicated. In Dr. Nixon's case, in which subtotal hysterectomy was performed by Dr. Deaver, the uterus presented five myomata, the largest of which contained irregular ragged cavities full of thick greenish pus, smears from which showed a Gram-negative intracellular diplococcus. The patient left the hospital in good condition 27 days after the operation.

SELECTION OF STUDENTS AT CROWDED MEDICAL SCHOOLS.

AT a recent meeting of the General Committee of University College Hospital the following resolution was passed regarding the admission of women students to the Medical School:—

> That during the session 1922-23 and in subsequent sessions the number of women students to be admitted to the Hospital and Medical School be limited to 12.

We understand that the circumstances in which this decision was taken were substantially these. The School Committee felt that there was an actual danger of the school becoming swamped by women students, and that if an undue proportion of women students were admitted there would be considerable risk of men students being driven away from the Medical School. It was recognised that the decision would entail some hardship upon women now taking their preliminary and intermediate medical subjects at University College, although admission to University College does not confer any presumptive right to admission to the Hospital. Eight of the 12 places allotted to women will be filled on the nomination of the authorities of University College and the remaining four will be thrown open to competitive examination. The resolution limiting the number of women students to 12 does not come into force until October, 1922, leaving an interval during which it may be expected that the non-selected students will obtain admission to some other hospital admitting women students. The entry of men students to the Medical School is also restricted by the size of the Hospital. At the present the School is only able to admit for the full course men who have completed their preliminary and intermediate studies at University College and a certain number of selected men from Oxford and Cambridge. The total number of students admitted in any one year cannot exceed 80 and it is interesting to compare the method of selection with that adopted by the University of Minnesota, which, as we learn from Dr. Norman Walker's report cited elsewhere, can also only admit 80 entrants annually. The following is the method adopted at Minnesota, which, in all its details, could not be followed in this country with success:—

> The Dean of the Medical Faculty had 400 inquiries from those who proposed to enter last autumn. By a strict scrutiny of the educational qualifications of the applicants, he reduced it to below 200. The answers were then considered to the schedule of inquiry sent out to those concerned with the candidate's earlier education and examination, including a report on personal appearance, manner with associates, initiative, ambition, industry, tact, use of oral and of written English. The Dean by this means reduced the numbers to something like 150. But still this did not get down to 80, and they then applied mental tests, and a series of examinations on the Binet method were applied to the residue. At the end of the first year unsuitable students are again weeded out, and advised either to give up medicine or to find some other place to study it in, their places being filled by students from schools which have as yet no clinical facilities and only give the first and second year's instruction in medicine.

Popular schools all have to adopt some kind of entrance filter and are evidently within their rights in selecting the material likely to benefit most fully from the educational facilities provided. The contrivance of the filter will, however, leave ample room for the tact and discretion of the authorities.

H.R.H. the Prince of Wales has announced his intention of being present at the Hunterian festival dinner of the Royal College of Surgeons of England to be held on Feb. 14th, when he will receive his diploma as Honorary Fellow.

THE appointment is announced of Mr. S. P. Vivian, a Principal Assistant Secretary in the Ministry of Health and Deputy Registrar-General, to be Registrar-General in succession to Sir Bernard Mallet, K.C.B.

FOUR lectures on Communicable Diseases will be delivered by Sir Robert Armstrong-Jones at Gresham College, Basinghall-street, London, E.C., on Jan. 25th and the three following days, at 6 P.M. Admission is free.

AMALGAMATION OF ROYAL CHEST HOSPITAL WITH GREAT NORTHERN CENTRAL HOSPITAL.—At a special meeting of the governors of the Royal Chest Hospital, City-road, held at the Mansion House on Jan. 17th, the scheme, noted last week, for the amalgamation of this hospital with the Great Northern Central Hospital, Holloway-road, was approved. The latter hospital is to provide a number of beds allocated to diseases of the heart and lungs at least equal to those given up by the Royal Chest Hospital, and a block is to be named the Royal Chest Hospital block. The City-road premises are to remain open until such time as building becomes practicable, when the in-patient block and the nurses' home will be disposed of; the out-patient and X ray departments will be retained. It is stated that proper provision will be made for the medical and lay staffs of the Chest Hospital.

TYPHUS IN TURKEY AND ADJOINING COUNTRIES:

ITS RECENT PREVALENCE.

BY F. G. CLEMOW, C.M.G., M.D.,
BRITISH DELEGATE, INTER-ALLIED SANITARY COMMISSIONS, CONSTANTINOPLE.

IN two earlier articles, published respectively in THE LANCET of Nov. 20th and Dec. 11th, 1920, brief accounts were given of the recent behaviour of plague and cholera in Turkey and some adjoining countries. In the present paper an attempt will be made to summarise the records, so far as they exist, of recent typhus prevalence in the same regions.

In Turkey the disease was rarely seen before the war, and in Constantinople it was scarcely known as an indigenous disorder. Since the outbreak of the war, however, it has become widely epidemic throughout the greater part of the country. Figures, more or less reliable, are available for the years 1916–19 inclusive, and these are quoted in the following table. These figures have been furnished by the Public Health Department of the Turkish Ministry of the Interior. They have a certain relative value, but can only be regarded as approximate, and must be accepted with the same (or even greater) reserve, as in the case of the analogous figures for plague and cholera. They are said to include both civil and military records:—

Typhus in Turkey in the Years 1916–19.

C. = cases; D. = deaths.

Totals	25525	6335	25139	4434	14745	2453	4261	519

The incompleteness of these figures is evident. Many of the blanks and "zeros" indicate, not that the disease was absent, but that the territory had passed out of Turkish possession, either temporarily or permanently. This, to a considerable extent, explains the lower totals for the last two years of the series. Moreover, since the Nationalist revolt in Asia Minor, the Turkish records have become more imperfect than ever, and are now almost confined to the returns for Constantinople itself. In the present year (1920) typhus again became epidemic in the capital in February, March, and April, mainly as a result of the influx of Russian refugees after the defeat of Denikin's army. The highest number of cases in any one week (that ending March 13th) was 78. In the summer the epidemic greatly declined but the disease never wholly disappeared. It has now again become active, with the arrival of a still larger crowd of refugees from the Crimea, after the collapse of Vrangel's army. About 100 cases have already been reported amongst them. Typhus, however, is not the disease from which this latest group of refugees is suffering most; relapsing fever is far more prevalent amongst them, and already the total number of known cases of the latter disease is not far short of 1000. The total number of cases of typhus in Constantinople during the year just closing will prove to be something between 600 and 700.

Winter Epidemics in South Russia.

In South Russia it has been known that typhus has been widely prevalent for some years past, and each recent winter it has caused an epidemic of considerable intensity. Exact figures, however, have for the most part not been available. The information received here from that country has been scanty and irregular, and it is only possible to quote occasional reports from reliable authorities, throwing more or less light on the degree of prevalence of the disease in certain places. Thus, in the winter of 1918–19 there was an epidemic of great severity. As late as April, 1919, it was known, from British sources, that 370 cases of typhus were in hospital in Novorossiisk, 460 in Batoum, and 200 in Alexandropol. The case mortality, however, was not high; it was estimated at about 3 per cent. only. The disease remained prevalent more or less throughout the rest of the year, and in January, 1920, it was again causing a severe epidemic. Exact figures were only occasionally received here; but it is known that in Novorossiisk alone, on Jan. 31st, 763 cases were in hospital; and in the week ending Feb. 7th 218 fresh cases were admitted to hospital, 193 were discharged, 75 died, and there were 872 (*sic*) remaining at the end of the week.

In March an interesting report was received from French sources upon the sanitary condition in South Russia. Novorossiisk, whose ordinary population numbered about 60,000, was then said to contain some 300,000 persons—mostly refugees from the Bolsheviks. In the Volunteer army, out of 45,000 sick and wounded, 33,000 were reported to be suffering from infectious diseases, and of these more than 25,000 were said to be cases of typhus. The hospitals were enormously overcrowded, and a harrowing account was given of the conditions in Novorossiisk, where large numbers of typhus cases were being treated in their houses, or dying in the trains, the stations, or even in the railway wagons, in which many of the population were living. In a later report the number of typhus cases outside the hospitals was estimated at about 15,000. Sevastopol was in much the same state. Its normal population was estimated at 50,000, and this figure had increased to 150,000 and the hospitals were full of typhus patients. The disease was also raging in other towns. The conditions prevailing at Kharkof, Rostof, Novotcherkask, Taganrog, and Ekaterinodar were said to be much the same as those at Novorossiisk and Sevastopol. The severity of the epidemic may be judged by the statement in a Kharkof medical journal that in that town alone 40 medical men died from typhus in two weeks in December, 1919. But other diseases also, and especially tuberculosis, were causing a high mortality everywhere. The lack of food, water, linen, coal, and all the other prime necessities of life were adding greatly to the sufferings of the people. Infant mortality was excessively high, and venereal diseases were reported to have taken on an immense extension.
